3. Disputationsgutachter: Prof. Dr. Eva Bamberg
4. Disputationsgutachter: Prof. Dr. Bernhard Dahme

When you discover new information or a broader context you have to throw out the old understanding, no matter how much sense it made to you. Getting it right in the future is more important than the feeling of understanding you had in the past. - Dr. Ben Tippet

#### Abstract

Data analysis, common to all empirical sciences, often requires complete data sets, but real-world data collection will usually result in some values being not observed. Many methods of compensation with varying degrees of complexity have been proposed to perform statistical inference when the data set is incomplete, ranging from simple ad hoc methods to approaches with refined mathematical foundation. Given the variety of techniques, the question in practical research is which one to apply. This dissertation serves to expand on a previous proposal of an imputation method based on Generalized Additive Models for Location, Scale, and Shape. The first chapters of the current contribution will present the basic definitions required to understand the Multiple Imputation field. Then the work discusses the advances and modifications made to the initial work on GAMLSS imputation. A quick guide to a software package that was published to make available the results is also included. An extensive simulation study was designed and executed expanding the scope of the latest published results concerning GAMLSS imputation. The simulation study incorporates a comprehensive comparison of multiple imputation methods.

## Chapter 1

## Introduction

Missing data is a problem that exists within virtually any discipline that makes use of empirical data. When performing longitudinal or cross-sectional studies in psychological research, it is not uncommon for data to be missing either by chance or by design. For instance, in research involving multiple waves of measurements, missing data can arise due to attrition, that is, subjects drop out before the end of the study.

Typically, researchers have many standard complete-data techniques available, many of which were developed early in the twentieth century like the ordinary least-squares regression and factor analysis (Seal, 1967), when there was just no solution for handling missing values. More modern techniques like the random effects model (Henderson et al., 1959) or the logistic regression (Cox, 1958) that became accessible before 1970 were also intended for complete data sets. Software packages like R, SAS, and SPSS provide these routines. However, these methods, being complete-data techniques, are not able of dealing correctly with incomplete data sets.

Simple solutions were in use for decades (Schafer and Graham, 2002). These strategies involved discarding incomplete cases or substituting missing data by somehow plausible values. The most popular approach is complete case analysis (CCA) also known as listwise deletion. The method is simple, and no particular modifications are needed. The main difficulty is that not all missing values have the same reason for not being observed, and there are situations in which missing data do not affect the conclusions, but generally, no justification is provided for the assumptions underlying the analysis at hand.

Neglecting the missing data problem can result in adverse consequences such as the loss of statistical power of a given analysis due to the reduction of the sample size, or even worse, missing values may invalidate the conclusions for the data and lead to wrong statistical inference. Today, disadvantages of these methods are well known in both the statistical and applied literature (Little and Rubin, 2002).

### 1.1 State of the Art

There are two primary schools about how to deal with the missing data problem. On one side, there are model-based methods mainly built around the formulation of the Expectation-Maximization (EM) algorithm made popular by Dempster, Laird, and Rubin (1977). This technique makes the computation of Maximum Likelihood (ML) estimator feasible in problems affected by missing data. In short, the EM algorithm is an iterative procedure that produces maximum likelihood estimates. The idea is to treat the missing data as random variables to be removed by integration from the log-likelihood function as if they were not sampled. The EM algorithm allows dealing with the missing data and parameter estimation in the same step. The major drawback of this model-based method is the requirement of the explicit modeling of joint multivariate distributions and, thus, tend to be limited to variables deemed to be of substantive relevance (Graham, Cumsille, and Elek-Fisk, 2003). Furthermore, this approach requires the correct specification of usually high-dimensional distributions, even of aspects which have never been the focus of empirical research and for which justification is hardly available. According to Graham (2009), the parameter estimators (means, variances, and covariances) from the EM algorithm are preferable over a wide range of possible estimators, based on the fact that they enjoy the properties of maximum likelihood estimation.

The second approach deals with model-based missing data procedures and was introduced by Rubin (1987) with his concept of Multiple Imputation (MI). Instead of removing the missing values by integration as EM does, MI simulates a sample of $m$ values from the posterior predictive distribution of the missing values given the observed. Each missing value is replaced by this approach with $m>1$ possible values, accounting for uncertainty in the values predicting the true but unobserved values. The substituted values are called "imputed" values, hence the term "Multiple Imputation."

MI can be summarized in three steps. The first step is to create $m$ sets of completed data by replacing each missing value with $m$ imputed values. The second phase consists of using standard statistical methods for separate analysis of each completed data set as if it were a "real" completely observed data set. The third step is the pooling step where the results from $m$ analyses are combined to form the final results and allows statistical inference in the usual way. This technique has become one of the most advocated methods for handling missing data.

The MI framework comprises three models: The complete data model, the nonresponse model, and the imputation model. The complete data model is the one used to make inferences of scientific interest. For example, a linear regression including
the outcome and explanatory variables of an experiment. The nonresponse model represents the process that leads to missing data. The covariates in the nonresponse model are not primarily of interest, and they are not necessarily part of the complete data model. The imputation model is the model from which plausible values for each missing datum are generated. A problematic step of MI procedures is the specification of the imputation model because the validity of the analysis of the complete data model strongly depends on how imputations are created. If the imputation model is not correctly specified, then final inferences may be invalid.

There are two ways of specifying imputation models: Joint modeling (JM) and fully conditional specification (FCS). Joint modeling involves specifying a multivariate distribution for the variables whose values have not been observed conditional on the observed data and then drawing imputations from this conditional distribution by Markov chain Monte Carlo (MCMC) techniques (Schafer, 1997). On the other hand, with the fully conditional specification, also known as multivariate imputation by chained equations (van Buuren and Groothuis-Oudshoorn, 2011), a univariate imputation model is specified for each variable with missings conditional on other variables of the data set. Initial missing values are imputed with a bootstrap sample, and then subsequent imputations are drawn by iterating over conditional densities (van Buuren, 2007; van Buuren and Groothuis-Oudshoorn, 2011).

Within the JM framework, Little and Rubin (2002), Rubin (1987), and Schafer (1997) have developed imputation procedures for multivariate continuous, categorical and mixed continuous and categorical data based on the multivariate normal, log-linear and general location model, respectively. There has also been development in univariate models for modeling semicontinuous data. Javaras and Dyk (2003) introduced the blocked general location model (BGLoM), designed for imputing semicontinuous variables with the help of EM and data augmentation algorithms.

Another device that can be used to generate imputations is nonparametric techniques, like hot deck methods. Based on hot deck methods, the missing values are imputed by finding a similar but observed unit, whose value serves as a donor for the record of the similar but incompletely observed unit. The most popular are k-nearestneighbor algorithms from which the best known method for generating hot-deck imputations is the Predictive Mean Matching (PMM) (Little, 1988), which imputes missing values employing the nearest-neighbor donor distance base on expected values of the missing variables conditional on observed covariates. There are several advantages of kNN imputation. It is a simple method that seems to avoid strong parametric assumptions, it can easily be applied to various types of variables to be imputed, and only available and observed values are imputed (e.g., Andridge and Little, 2010; Little, 1988; Schenker and Taylor, 1996). However, the final goal of the complete data
statistical analysis is to make inferences about the population represented by the sample; therefore, the plausibility of imputed values is not the defining factor in choosing an imputation model over another. Instead, the proper criterion is the validity of the final analysis of scientific interest.

Recent research on improving the performance of kNN methods focused on the distance function and the donor selection. Tutz and Ramzan (2014) proposed a weighted nearest neighbor method based on $L_{q}$-distances and Siddique and Belin (2008) and Siddique and Harel (2009) propose a multiple imputation method using a distanceaided selection of donors (MIDAS). The latter technique was extended and implemented in R by Gaffert, Meinfelder, and Bosch (2016). Harrell (2015) proposed the aregImpute algorithm which combines aspects of model-based imputation methods in the form of flexible nonparametric models with the predictive mean matching.

Modern methods like Amelia (Honaker, King, and Blackwell, 2011) or irmi (Templ, Kowarik, and Filzmoser, 2011) and even hot deck methods like PMM (Little, 1988) make use of linear imputation models explicitly or implicitly. However, the conditional normality of the dependent variable in a homoscedastic linear model with incompletely observed metric predictors alone is not sufficient to justify a linear imputation model for the incompletely observed variable. Thus, assumed linear imputation models would not, in general, be compatible with the true data generating process. Although it has been proposed to transform variables to assume multivariate normality more plausible (e.g., Honaker, King, and Blackwell, 2011; Schafer, 1997), this technique does not work in general (e.g., Hippel, 2013). The distribution of variables in the observed part of the data set might be very different from the distribution of the same variables if there were no missing values. In an experiment, Hippel (2013), showed that transformed imputation models led to biases in the estimators.

A newly proposed method by de Jong (2012) and de Jong, van Buuren, and Spiess (2016) makes use of Generalized Additive Models for Location Scale, and Shape (GAMLSS). The proposed method fits a nonparametric regression model with spline functions as a way of specifying the individual conditional distribution of the variables with missing values which can be used in the framework of chained equations. Roughly, the idea is to use semi-parametric additive models based on the penalized log-likelihood and then fit the conditional parameters for location, scale, and shape using a smoother. In principle, the specification of the conditional distribution can be arbitrary, though de Jong, van Buuren, and Spiess (2016) mainly used the normal distribution.

### 1.2 Strengths and weaknesses of multiple imputation procedures

An important notion concerning the success of the method of multiple imputation is the hypothesis of "proper" multiple imputation. The concept of proper imputations is based on a set of conditions imposed on the imputation procedure. An imputation method tends to be proper if the imputations are independent draws from an appropriate posterior predictive distribution of the variables with missing values given all other variables (Rubin, 1987). This implies, that both, the average of the $m$ point estimators is a consistent, asymptotically normal estimator of the parameter of scientific interest and that an estimator of its asymptotic variance is given by a combination of the within and between variance of the point estimators. Meng (1994) showed the consistency of the multiple imputation variance estimator as the number of imputations tends to infinity but restricted his analysis to "congenial" situations, in which imputation and analysis models match each other in a certain sense. In contrast, Nielsen (2003) claims that MI "is inefficient even when it is proper."

According to Rubin (1996), there are two distinct points of interest about multiple imputation. The first type focus on its implementation: operational difficulties for the imputer and the ultimate user, as well as the acceptability of answers obtained partially through the use of simulations. The second type concerns the frequentist validity of repeated-imputation inferences when the multiple imputation is not proper but seems "reasonable" in some sense. Rubin (1996) states that statistical validity, according to the frequentist definition, is difficult because it requires both that the imputation model with the assumptions considered by the imputer are correct and the complete-data analysis would have been already valid if there were to missing values ("Achievable Supplemental Objective", Rubin, 1996).

Rubin (2003) acknowledged that there are reasons for concerns about the methods since it is not yet proven in a strict mathematical sense that the multiple imputation method allows valid inferences in all situations of interest. Many statements are based on heuristics and simulation results, and there is almost always some uncertainty in choosing the correct imputation model. On the other hand, according to Rubin (2003), multiply-imputed data analyses using a reasonable but imperfect model can be expected to lead to slightly conservative inferences, that is, inferences that have coverage that is slightly larger than the nominal $(1-\alpha)$ percent. Theoretical arguments, as well as some empirical results based on simulations, imply that standard multiple imputation techniques may be rather robust concerning slight misspecifications of the imputation model, probably leading to larger confidence intervals and overestimation of variances. This is called the "self-correcting" property of mul-
tiple imputation methods (e.g., Little and Rubin, 2002; Rubin, 1996, 2003). Robins and Wang (2000) question the validity of the variance estimator proposed by Rubin (1987) and claim that in large samples the MI variance estimator may be downward biased.

Most results about individual imputation methods rely on simulated experiments. Schafer (1997) and Schafer and Graham (2002) argue that simulations or artificial experiments are a helpful instrument to investigate the properties of MI-based inferences since, by definition, these methods are based on random draws from a posterior distribution, akin to the application of Markov chain Monte Carlo routines. There are many examples of recent studies that based their results on simulations. Deng et al. (2016) developed an imputation method based on regularized regressions that presented a small bias but acceptable coverage rates in a simulation experiment. Donneau et al. (2015a,b) ran two comparison studies of multiple imputation methods for monotone and non-monotone missings patterns in ordinal data which found that normal assumptions for MI resulted in biased results. Kropko et al. (2014) compared the JM and FCS imputation approaches for continuous and categorical data, reporting better results for FCS.

He and Raghunathan (2009) evaluated the performance and sensitivity of several imputation methods to deviations from their distributional assumptions. They found that, concerning the estimation of regression coefficients, currently used multiple imputation procedures can, in fact, give worse performance than complete case analyses that ignore the missing mechanism about bias and variance estimation under seemingly harmless deviations from standard simulation conditions. Yu, Burton, and Rivero-Arias (2007) and then Vink et al. (2014) appraised the performance of multiple imputation software on semicontinuous data with mixed results showing that departures from linear or normality assumptions yielded worse estimates in general. They concluded that the most reliable methods were based on PMM, but de Jong (2012) and de Jong, van Buuren, and Spiess (2016) show that this is not necessarily true. They find that PMM can systematically underestimate the standard errors, leading to invalid inferences. To sum up, it is not yet known which imputation technique is most appropriate in which situation, and which is flexible and robust enough to work in a broad range of possible applications. One goal of the current work is to enhance the GAMLSS imputation method and perform extensive simulation experiments under a broad spectrum of experimental and practically relevant conditions.

### 1.3 Research goals

The GAMLSS approach defined in de Jong, van Buuren, and Spiess (2016) models additively individual location parameters like the conditional means of the variables to be imputed based on spline functions, which allows more flexibility than with standard imputation methods. An error term randomly selected from a normal distribution is added to generate imputations.

Simulation results in de Jong (2012) and de Jong, van Buuren, and Spiess (2016) imply that inferences tend to be valid adopting this imputation technique, even if the real underlying distribution of the covariables is Poisson or Chi-square. De Jong (2012) concluded that if the variable with missings is heavy-tailed like a Student's $t$, the imputation method may not be proper anymore, leading to severely underestimated variances of the estimators of scientific interest. Posterior analyses show that the same could happen with a missing mechanism thinning out specific regions in the data set.

A solution to this problem could be to replace the normal model for the error term with a more general family of distributions like the four-parameter Johnson SU family that in addition to the mean and variance also accounts for skewness and kurtosis of the actual error distribution.

Objective 1: Therefore, the first objective of this work is to relax the distributional assumption of the error within the GAMLSS imputation method to distributions with unknown mean, variance, skewness, and kurtosis.

A limiting feature of the simulation results in previous works for the GAMLSS imputation method is that the method was mostly tested in bivariate data sets and only one multivariate experiment where the variables were all independent and normally distributed. Also, there was always only one variable incompletely observed. Realworld applications require robust methods capable of dealing with complex data sets, where the variables are not independent of each other and interactions exist.

Objective 2: Thus, the second objective is to extend the GAMLSS-based imputation methods to the multivariate case and evaluate them concerning the validity of parameter estimators of scientific interest.

For the developed methods and algorithms to be helpful, it is necessary to show that they allow valid inference when used in applications. Analyzing the large-sample properties of the new method in an MI scenario proves to be very difficult. However, the growing use of computational statistics allows the use of Monte Carlo simulation as an alternative way to analyze the properties of the proposed method.

Objective 3: The final objective is to perform extensive empirical comparisons of the two GAMLSS approaches with available modern techniques via simulation exper-
iments to allow justified guidance in applied in empirical sciences.
This is an important point in current research since if a self-correcting property of MI holds, misspecification of imputation models would have only a minor effect on the validity of inferences with increasing sample sizes and therefore is of interest to test such relationship.

### 1.4 Outline of the dissertation

The first two chapters of the dissertation discuss the basic theoretical inferential aspects of the missing data problem. Chapter 2 introduces the model of scientific interest and taxonomy of the missing data mechanisms. The ignorability of the missing mechanism and the validity of complete-data procedures are also discussed. Chapter 3 focuses on the validity of Rubin's MI estimators and the steps required to perform standard statistical inference. Some topics like the number of imputations and the available methods for multivariate data sets are also discussed.

Chapter 4 describes some of the most used imputation methods imputation methods. Chapter 5 presents the GAMLSS-based imputation method. The experimental design and results of the comparison will be discussed in Chapter 6.

## Chapter 2

## Statistical Inference with partially observed data sets

Real-world data sets often are only partially observed. This chapter discuss aspects of the statistical inference and general concepts related to the missing data problem. Section 2.1 presents the model of scientific interest, and discusses how to address the consistent and valid estimation of its parameters. Most importantly, the section introduces the concepts of Complete Case Analysis and Multiple Imputation, and defines the notation to be used in the manuscript. Section 2.2 formalizes a classification of the Missing Data Mechanisms (MDM). Section 2.3 discusses the effect of assumptions of the missing data mechanism when estimating the parameters in a regression model.

### 2.1 Why Multiple Imputation

Let's suppose that given $Y=\left(Y_{i j}\right), i=1, \ldots, n$ and $j=1, \ldots, p$, a matrix with the observations for $n$ units on $p$ variables we want to make inferences about the vector of population parameters $\theta^{T}=\left(\theta_{1}, \ldots, \theta_{p}\right)$. We define the model

$$
\begin{equation*}
\mathrm{E}\left[U\left(Y_{i}, \theta\right)\right]=0, \tag{2.1}
\end{equation*}
$$

where $U$ is a $(p \times 1)$ real-valued function. This is actually a just-identified Generalized Method of Moments (GMM) model and with different choices of $U$, encompasses many common used applications like linear and nonlinear regression models, maximum likelihood estimation or instrumental variable regression (Cameron and Trivedi, 2005, Chapter 6).

The objective of statistical research is to provide valid inference about $\theta$. Assuming that the data is fully observed, Cameron and Trivedi (2005) show that consistent and
valid estimators $\widehat{\theta}$ and $\widehat{\Sigma}$ for the model in equation (2.1) can be obtained as:

$$
\begin{align*}
& \widehat{\theta}=\operatorname{argmin}_{\theta}\left[\frac{1}{n} \sum_{i}^{n} U\left(Y_{i}, \theta\right)\right]^{T}\left[\frac{1}{n} \sum_{i}^{n} U\left(Y_{i}, \theta\right)\right],  \tag{2.2}\\
& \widehat{\Sigma}=\left[\frac{\partial \sum_{i}^{n} U\left(Y_{i}, \theta\right)}{\partial \theta}\right]^{-1} \sum_{i}^{n} \sum_{i^{\prime}}^{n} U\left(Y_{i}, \theta\right) U\left(Y_{i^{\prime}}, \theta\right)^{T}\left[\left(\frac{\partial \sum_{i}^{n} U\left(Y_{i}, \theta\right)}{\partial \theta}\right)^{T}\right]^{-1} . \tag{2.3}
\end{align*}
$$

Let's suppose that the data $Y$ is only partially observed. The observed and missing parts of variable $Y_{j}$ are denoted by $Y_{j}^{\text {obs }}$ and $Y_{j}^{\text {mis }}$, respectively. Let's define the missing indicator, $R$, as binary matrix representing the missing data pattern. For each individual unit $i$ and variable $j$, let $R_{i j}=1$ if $Y_{i j}$ is observed and $R_{i j}=0$ if $Y_{i j}$ is missing.

One naive approach to still perform the statistical analysis in the presence of missing values is to use complete case analysis (CCA). This method would delete all units with missing values, i.e., remove unit $Y_{i}$ if $\exists j: R_{i j}=0$. The estimators $\widehat{\theta}$ and $\widehat{\Sigma}$ would still be obtained through equations (2.2) and (2.3) replacing $Y$ by the reduced, but fully observed, data set $Y^{\text {obs }}$. Whether CCA keeps consistency and validity of the estimators is a different matter. The answer to that problem depends on the specific statistical analysis and the underlying mechanism that led to some values not being observed. Example of this are discussed in section 2.3.

Using the Law of Iterated Expectations in model (2.1), a consistent estimator of $\theta$ without ignoring incompletely observed data, as with CCA, can be obtained from solving:

$$
\begin{equation*}
\mathrm{E}_{f\left(Y^{m i s \mid Y o b s}, R\right)}\left[U\left(Y^{o b s}, Y^{m i s}, \theta\right)\right]=0 . \tag{2.4}
\end{equation*}
$$

where $\left(Y^{o b s}, Y^{\text {mis }}\right)$ is a partition of the data set into its observed and missing parts and $f\left(Y^{m i s} \mid Y^{o b s}, R\right)$ is the conditional predictive distribution of the missing data. If $U(\cdot)$ is the score function, a consistent estimator of the covariance matrix of $\theta$ using the Fisher-information matrix. This can be obtained with Louis's formula (Louis, 1982):

$$
\begin{align*}
\mathscr{I}(\theta) & =\mathrm{E}_{\theta}\left[\frac{\partial U(Y, \theta)}{\theta}\right] \\
& -\mathrm{E}_{f\left(Y^{m i s} \mid Y o b s, R\right)}\left[U(Y, \theta) U(Y, \theta)^{T}\right] \\
& +\mathrm{E}_{f\left(Y^{m i s} \mid Y o b s, R\right)}[U(Y, \theta)] \mathrm{E}_{f\left(Y^{m i s} \mid Y o b s, R\right)}[U(Y, \theta)]^{T} \tag{2.5}
\end{align*}
$$

The actual usefulness of equations (2.4) and (2.5) in specific applications differs notably. Even for standard regression problems with incomplete data there are no general solution methods and unique solutions have to be developed, often quite complex and of limited use. For example, Elashoff and Ryan (2004) propose a solution based on the EM algorithm that require the specification of additional moment conditions
to characterize the conditional expectations of the missing data. Approaches like this become quickly unmanageable as the models get more complex than a standard regression (Carpenter and Kenward, 2012).

Multiple Imputation (Rubin, 1987) will provide an indirect way to solve the estimation problem. The key idea behind it is to reverse the order of the expectation and estimation in equation (2.4). The essence is to repeat the following steps:

1. draw $\widetilde{Y}^{\text {mis }}$ from $f\left(Y^{m i s} \mid Y^{o b s}, R\right)$,
2. solve $\mathrm{E}\left[U\left(Y^{o b s}, Y^{m i s}, \theta\right)\right]=0$.
and combine the results somehow to perform the inference. This provides an alternative to complex methods, allowing the use of the "complete data" methods given by equations (2.2) and (2.3) in the estimation step. The $\widetilde{Y}^{\text {mis }}$ imputed values are draws from the Bayesian conditional predictive distribution of the missing observations. The model, $f$, used to produce the imputations is called the "imputation model". One of the advantages of the MI method is that the model of scientific interest and the imputation model can be fitted separately. The combination rules and the justification of this method is discussed in chapter 3.

### 2.2 Missing Data Mechanism

The performance of missing data techniques strongly depends on the mechanism that generated the missing values. Standard methods for handling missing values usually make implicit assumptions about the nature of these causes. The missing data mechanism can be defined as

$$
\begin{equation*}
\mathrm{P}\left(R_{i} \mid Y_{i}, \psi\right), \tag{2.6}
\end{equation*}
$$

which is the probability of observing the values of $Y_{i}$ given their actual data and a vector of parameters, $\psi$, of the underlying missing mechanism. An implicit assumption being made is that the values of $Y_{i j}$ exist regardless of whether they are observed or not.

The focus of the model of scientific interest in section 2.1 is estimation of $\theta$. The parameter $\psi$ of the missing mechanism in equation (2.6) has no innate scientific value and therefore it makes sense to ask if and when its estimation could be safely ignored. Rubin $(1976,1987)$ formalized a system of missing mechanisms that classify missing data problems in three categories: missing data either being missing completely at random (MCAR), missing at random (MAR) or missing not at random (MNAR).

To exemplify the different classes, let's consider an hypothetical clinical trial on the effects of a given drug for the treatment of depression. In this study 200 patients with
depression are randomly assigned to one of two groups, one with an experimental drug and the other with a placebo. Participants completed a depression scale, e.g., HAMD (Hamilton, 1964) or BDI (Beck et al., 1996) after the end of treatment. Let $Y_{1}$ take on values 0 and 1 if participants were in the placebo or treatment group respectively, and $Y_{2}$ be the depression scores after the treatment. Some of the values of $Y_{2}$ are missing according to the following mechanism

$$
\begin{equation*}
\mathrm{P}\left(R_{i 2}=0\right)=\psi_{0}+\left[0.3 Y_{i 1}+0.9\left(1-Y_{i 1}\right)\right] \psi_{1}+\left(1-\frac{Y_{i 2}}{8+Y_{i 2}}\right) \psi_{2} \tag{2.7}
\end{equation*}
$$

which is just an example that based on the values of $\psi_{0}, \psi_{1}$, and $\psi_{2}$ will help to illustrate the different types of missing mechanism.

### 2.2.1 Missing Completely At Random (MCAR)

Missing data is said to be MCAR if the probability of the observed pattern of observed and missing data does not depend on any of the other variables relevant to the analysis of scientific interest, observed or not. Mathematically this can be expressed as,

$$
\begin{equation*}
\mathrm{P}\left(R_{i} \mid Y_{i}, \psi\right)=\mathrm{P}\left(R_{i} \mid \psi\right) \tag{2.8}
\end{equation*}
$$

The MCAR mechanism exemplifies an event where missing values happen entirely by chance, and it is a rather strong assumption.

Suppose that, in the example, we wish to estimate the mean depression rating at the end of the study given the treatment group. The participants flipped a coin, and based on the outcome decided whether to fill out the questionnaire at the end of the study. The same can be expressed with equation (2.7) by setting $\psi=(0.5,0,0)$ leading to

$$
\mathrm{P}\left(R_{i 2}=0\right)=0.5
$$

In this scenario the missing values are MCAR and since the probability of not being observed is unrelated to the values of $Y_{1}$ or $Y_{2}$, the observed part of the data is nonselective with respect to the population. Valid inferences can be obtained from the observed values.

### 2.2.2 Missing at Random (MAR)

The missing mechanism is MAR if the probability does depend on observed values of the relevant variables but not additionally on relevant unobserved values of variables. If $Y_{i}$ is partitioned as $\left(Y_{i}^{o b s}, Y_{i}^{\text {mis }}\right)$, representing the observed and unobserved parts of
$Y_{i}$, then

$$
\begin{equation*}
\mathrm{P}\left(R_{i} \mid Y_{i}, \psi\right)=\mathrm{P}\left(R_{i} \mid Y_{i}^{o b s}, \psi\right) . \tag{2.9}
\end{equation*}
$$

The MAR mechanism is considerably weaker than the MCAR. Equation (2.9) doesn't imply that the probability of observing a variable is independent of its value. What the MAR assumption means is that conditional on the observed data, the probability of observing a variable doesn't depends on its value.

Figure 2.1: Plot of hypothetical depression rating scale values against treatment group
Let's continue with the depression rating example. Figure 2.1 shows a scenario where $\psi=(0,1,0)$ in equation (2.7), leading to the missing mechanism

$$
\begin{equation*}
\mathrm{P}\left(R_{i 2}=0\right)=0.3 Y_{i 1}+0.9\left(1-Y_{i 1}\right), \tag{2.10}
\end{equation*}
$$

meaning that participants in the placebo group are less likely to complete the questionnaire at the end of the study as compared with participants in the drug group, that is, given the value of $Y_{i 1}$, the probability of missing $Y_{i 2}$ is either 0.9 or 0.3 independent of its value conditional on the treatment group. This means that the missing scores at the end of the study are MAR conditional on the treatment group. A consequence of this missing data mechanism is that the estimation of the marginal mean will be
downward biased. A hypothetical data set was simulated with arbitrary mean depression scores of 9 and 15.5 for the drug and placebo groups respectively, so that the true marginal mean is 12.25 . However, the observed mean is

$$
\begin{equation*}
(94 \times 8.96+33 \times 14.47) / 127=10.39 \tag{2.11}
\end{equation*}
$$

based on the values recorded in Figure 2.1.
Due to the missing depression scores being MAR conditional on the treatment group, it can be shown that the distribution of unobserved and observed ratings is the same within each treatment group. Mathematically,

$$
\begin{align*}
\mathrm{P}\left(Y_{i 2} \mid Y_{i 1}, \psi, R_{i 2}=0\right) & =\frac{\mathrm{P}\left(Y_{i 1}, Y_{i 2}, \psi, R_{i 2}=0\right)}{\mathrm{P}\left(Y_{i 1}, \psi, R_{i 2}=0\right)} \\
& =\frac{\mathrm{P}\left(R_{i 2}=0 \mid Y_{i 1}, Y_{i 2}, \psi\right) \mathrm{P}\left(Y_{i 1}, Y_{i 2}, \psi\right)}{\mathrm{P}\left(R_{i 2}=0 \mid Y_{i 1}, \psi\right) \mathrm{P}\left(Y_{i 1}, \psi\right)} \\
& =\mathrm{P}\left(Y_{i 2} \mid Y_{i 1}, \psi\right), \tag{2.12}
\end{align*}
$$

using the fact that missing depression scores are MAR conditional on treatment group in the last equality, since

$$
\begin{equation*}
\mathrm{P}\left(R_{i 2}=0 \mid Y_{i 1}, Y_{i 2}, \psi\right)=\mathrm{P}\left(R_{i 2}=0 \mid Y_{i 1}, \psi\right) \tag{2.13}
\end{equation*}
$$

The same claim is valid for $R_{i 2}=1$, so the distribution of depression scores given treatment group is the same in the observed and unobserved data, and the population.

The argument presented is akin to say that within treatment groups, depression rating is MCAR. We can use that fact to estimate the marginal mean, scaling up the averages of the mean in each group to yield a better estimate,

$$
\begin{equation*}
(100 \times 8.96+100 \times 14.47) / 200=11.71 \tag{2.14}
\end{equation*}
$$

This is equivalent to replace the missing values in each of the treatment groups by the mean of the group.

Two further points need to be made. First, under the MAR assumption, the exact details of the missing mechanism, such as the $\psi$ parameter, don't have to be specified (Carpenter and Kenward, 2012). Second, it's important to notice that the assumption of the depression score being MAR (or MCAR) given the treatment group is an untestable claim. The data needed to test is, of course, missing.

### 2.2.3 Missing Not At Random (MNAR)

Finally, the unobserved data is MNAR if the probability of the pattern of observed and missing data does depend not only on observed but also on unobserved values of variables relevant to the research question, that is,

$$
\begin{equation*}
\mathrm{P}\left(R_{i} \mid Y_{i}, \psi\right) \neq \mathrm{P}\left(R_{i} \mid Y_{i}^{o b s}, \psi\right) \tag{2.15}
\end{equation*}
$$

If in our depression study example, we let $\psi=(0,0,1)$, the missing mechanism (2.7) turns into

$$
\mathrm{P}\left(R_{i 2}=0\right)=1-\frac{Y_{i 2}}{8+Y_{i 2}}
$$

which means that participants with higher values of depression scores, or side-effects from the experimental drug are more likely not to be present at the end of the study. Then the probability of observing a value it is dependent on the value itself, like in the missing mechanism shown, where the response indicator of $Y_{2}$ depends on $Y_{2}$. This defines a MNAR mechanism.

Although it seems like the MNAR assumption could be more likely in real-world applications than MAR, statistical analyses are far more difficult. Under MAR, equation (2.13) shows that the conditional distribution of partially observed variables coincide for units with observed and unobserved values. This is not true under MNAR.

### 2.2.4 Ignorability

The classification system of Rubin (1976) define conditions under which $\theta$ can be accurately estimated without being affected by ignoring $\psi$. According to Little and Rubin (2002, Section 5.3), the missing data mechanism is ignorable if the missing data are at least MAR and the joint parameter space $(\theta, \psi)$ is the product of the parameter spaces of $\theta$ and $\psi$, that is, $\theta$ and $\psi$ are distinct. Since the model of scientific interest is not the missing data mechanism itself and usually knowing $\theta$ will add little information about $\psi$ and the other way around according to Schafer (1997), the MAR requirement is considered the most important condition (van Buuren, 2012).

More precisely, a valid analysis can be constructed without the necessity of explicitly including the model for the missing data mechanism. In the context of this analysis, the missing mechanism can be ignored when applying the method of imputation to compensate for missing data.

A consequence of the concept of ignorability is represented by equation (2.12) which implies that

$$
\mathrm{P}\left(Y^{m i s} \mid Y^{o b s}, R=1\right)=\mathrm{P}\left(Y^{m i s} \mid Y^{o b s}, R=0\right) .
$$

Hence, if the missing data mechanism is ignorable, the conditional predictive distribution in equation (2.4), $f\left(Y^{m i s} \mid Y^{o b s}, R\right)$ can be modeled with just the observed data.

On the other hand, if missing data are MNAR, then the missing mechanism can not be ignored, and strong assumptions or external knowledge is usually necessary to compensate for the missing data. The focus of the current research will be on ignorable missing mechanisms.

### 2.3 Estimation of parameters with partially observed data

It is of importance to analyze the connotations of the missing data mechanism for the estimation of $\theta$, the parameter in the scientific model of interest. The argument about ignorability of $\psi$, the parameter of the MDM, does not imply a one-to-one relationship between the type of missing mechanism and the validity of CCA.

Let's assume that we have a data set with two variables, $Y=\left(Y_{1}, Y_{2}\right)$ and the estimating equations, $U_{i}$, in equation (2.1) are $U_{i}\left(\theta, Y_{i}\right)=Y_{i 1}\left(Y_{i 2}-\theta_{0}-Y_{i 1} \theta\right)$. This formulation is equivalent to the scientific model of interest being the linear regression of $Y_{2}$ on $Y_{1}$. Simplifying, we wish to fit the model

$$
\begin{equation*}
Y_{i 2}=\theta_{0}+\theta_{1} Y_{i 1}+\epsilon_{i}, \quad \epsilon_{i} \sim N\left(0, \sigma^{2}\right) . \tag{2.16}
\end{equation*}
$$

We will consider next, the consequences of missing values in the response or covariates under different missing data mechanism with respect to bias and loss of information of the CCA.

### 2.3.1 Incompletely observed response

Let's suppose that $Y_{i 2}$ in equation (2.16) is incompletely observed, while $Y_{i 1}$ is fully known. The share in the likelihood of $\theta=\left(\theta_{0}, \theta_{1}\right)$ from unit $i$ conditional on $Y_{i 1}$ is

$$
\begin{equation*}
L_{i}=\mathrm{P}\left(R_{i 2}, Y_{i 2} \mid Y_{i 1}\right)=\mathrm{P}\left(R_{i 2} \mid Y_{i 2}, Y_{i 1}\right) \mathrm{P}\left(Y_{i 2} \mid Y_{i 1}\right) . \tag{2.17}
\end{equation*}
$$

Typically, the parameters of $\mathrm{P}\left(Y_{i 2} \mid Y_{i 1}\right), \theta$, are distinct from the parameter $\psi$ (see Schafer, 1997). If in addition, $Y_{2}$ is at least MAR with respect to $Y_{1}$ then the units with missing response carry no information about $\theta$. First, the MAR assumption makes $\mathrm{P}\left(Y_{i 2} \mid Y_{i 1}\right)$ the only term in the likelihood that involves $Y_{2}$. Second, the contributions
to the likelihood of the individual with missing response is

$$
\begin{equation*}
\int \mathrm{P}\left(Y_{i 2} \mid Y_{i 1}\right) d Y_{i 2}=1 \tag{2.18}
\end{equation*}
$$

integrating over all possible values of $Y_{i 2}$ given $\theta$ and $Y_{i 1}$, with the consequence of unobserved values of $Y_{2}$ having no effect in the likelihood estimation. The consequence is that CCA is valid in this scenario.

In case that the missing values of $Y_{2}$ are MNAR, the missing mechanism $\mathrm{P}\left(R_{i 2} \mid Y_{i 2}, Y_{i 1}\right)$ can not be ignored in equation (2.17) and therefore CCA is no longer valid.

### 2.3.2 Incompletely observed covariates

Let's reverse the scenario and assume that $Y_{i 2}$ is fully observed while $Y_{i 1}$ is not. Following the same procedure as in equation (2.12), for each unit $i$,

$$
\begin{align*}
\mathrm{P}\left(Y_{i 2} \mid Y_{i 1}, R_{i 1}=1\right) & =\frac{\mathrm{P}\left(Y_{i 1}, Y_{i 2}, R_{i 1}=1\right)}{\mathrm{P}\left(Y_{i 1}, R_{i 1}=1\right)} \\
& =\frac{\mathrm{P}\left(R_{i 1}=1 \mid Y_{i 1}, Y_{i 2}\right) \mathrm{P}\left(Y_{i 1}, Y_{i 2}\right)}{\mathrm{P}\left(R_{i 1}=1 \mid Y_{11}\right) \mathrm{P}\left(Y_{i 1}\right)} \\
& =\left[\frac{\mathrm{P}\left(R_{i 1}=1 \mid Y_{i 1}, Y_{i 2}\right)}{\mathrm{P}\left(R_{i 1}=1 \mid Y_{i 1}\right)}\right] \mathrm{P}\left(Y_{i 2} \mid Y_{i 1}\right) \tag{2.19}
\end{align*}
$$

This implies that if the missing mechanism for $Y_{1}$ includes the response $Y_{2}$, CCA will lead to biased estimation and invalid inference. This is true even if the missing mechanism is MAR with respect to $Y_{2}$, regardless of the inclusion of $Y_{1}$.

On the other hand, if the missing mechanism doesn't depend on the response, $Y_{2}$, then $\mathrm{P}\left(Y_{i 2} \mid Y_{i 1}, R_{i 1}=1\right)=\mathrm{P}\left(Y_{i 2} \mid Y_{i 1}\right)$ for all units, meaning that the distribution of the complete cases is the same as that in the population. As a consequence, CCA is valid, even if $Y_{1}$ is MNAR.

### 2.3.3 Discussion of assumptions

Subsections 2.3.1 and 2.3.2 show that restricting the regression analysis to the complete cases is invalid in general if the missing mechanism depends on the response variable. The presentation is illustrative of the importance of considering which variables are present in the missing mechanism, instead of only focusing on which are incompletely observed. Furthermore, additional considerations must be also taken into account when deciding to impute missing values. Ignoring altogether the missing mechanism requires the assumption that the missing values are MCAR or at least MAR.

An intrinsic problem of multiple imputation entails that the validity of the assumptions for the missing mechanism can not be tested. Taking ignorability for granted when in fact the data is MNAR will make the inference invalid. Possible remedies are the inclusion of additional predictors in the imputation models (Schafer, 1997) or performing a sensitivity analysis (Carpenter and Kenward, 2012).

In this contribution it will be assumed that the missing values are MAR with respect to the observed variables. In addition, the missing mechanism will generally include the response, making CCA invalid.

## Chapter 3

## Multiple Imputation

Rubin (1987) developed the theory of Multiple Imputation. The primary application at the time was to missing data in sample surveys and therefore, his initial work was formally directed to design based theory with some ideas on how to extend it to classical model based inference. Later, with the work of Meng (1994), Nielsen (2003), Robins and Wang (2000), and Wang and Robins (1998), much work was done to provide frequentist justification and results to the MI method.

This chapter defines the MI procedure to estimate the parameters of a model of scientific interest and discuss its justification and properties. Section 3.1 introduces the pooling rules of the MI method. Section 3.2 discusses the statistical validity of the MI estimators, providing necessary and sufficient conditions. Sections 3.3 and 3.4 provide guidelines for frequentist inference of incomplete data sets and how many imputations to create. Finally, section 3.5 extends the MI method to the analysis of multivariate data sets.

### 3.1 Combining rules

To fit the model in equation (2.4) using MI, the missing observations are replaced by imputed values, producing $M$ complete data sets. The $M$ complete data sets are analyzed with a standard complete data procedure, giving $\widehat{\theta}_{i}$ and $\widehat{\Sigma}_{i}, i=1, \ldots, M$, estimating of $\theta$ and its covariance matrix $\Sigma$. Finally, the estimates are combined according to Rubin's rules (Rubin, 1987, p. 67).

The estimate of $\theta$ is the mean of the $\widehat{\theta}_{i}$ estimates:

$$
\begin{equation*}
\widehat{\theta}_{M I}=\frac{1}{M} \sum_{i=1}^{M} \widehat{\theta}_{i}, \tag{3.1}
\end{equation*}
$$

and the estimate of the covariance matrix $\Sigma$ is given by:

$$
\begin{equation*}
\widehat{\Sigma}_{M I}=\widehat{W}+\left(1+\frac{1}{M}\right) \widehat{B}, \tag{3.2}
\end{equation*}
$$

where $\widehat{W}$ is the within-imputation covariance matrix

$$
\begin{equation*}
\widehat{W}=\frac{1}{M} \sum_{i=1}^{M} \widehat{\Sigma}_{i}, \tag{3.3}
\end{equation*}
$$

and $\widehat{B}$ the between-imputation covariance matrix of $\widehat{\theta}_{i}$

$$
\begin{equation*}
\widehat{B}=\frac{1}{M-1} \sum_{i=1}^{M}\left(\widehat{\theta}_{i}-\widehat{\theta}_{M I}\right)\left(\widehat{\theta}_{i}-\widehat{\theta}_{M I}\right)^{T} . \tag{3.4}
\end{equation*}
$$

Rubin (1987) shows that the formulas for the estimators can be justified by writing the posterior distribution of the $\theta$ parameters given the observed data, $\mathrm{P}\left(\theta \mid Y^{o b s}\right)$ as

$$
\begin{equation*}
\mathrm{P}\left(\theta \mid Y^{o b s}\right)=\int \mathrm{P}\left(\theta \mid Y^{o b s}, Y^{m i s}\right) \mathrm{P}\left(Y^{m i s} \mid Y^{o b s}\right) d Y^{m i s} \tag{3.5}
\end{equation*}
$$

where $\mathrm{P}\left(Y^{m i s} \mid Y^{o b s}\right)$ is the conditional predictive distribution of the missing data given the observed data and $\mathrm{P}\left(\theta \mid Y^{o b s}, Y^{\text {mis }}\right)$ is the posterior distribution of $\theta$ given the complete data.

Equation (3.5) suggests that the posterior distribution of $\theta$ is the average of the repeated draws of $\theta$ given the completed data ( $Y^{o b s}, Y^{m i s}$ ), where $Y^{\text {mis }}$ is drawn from its posterior distribution given $Y^{o b s}$. This is the main reason in favor of MI inference, since it expresses the posterior of $\theta$ given the observed data as the combination of two simpler posteriors, one being determined by a known complete data procedure and the other by the imputation model.

The posterior mean of $\mathrm{P}\left(\theta \mid Y^{o b s}\right)$ can be written as

$$
\begin{equation*}
\mathrm{E}\left(\theta \mid Y^{o b s}\right)=\mathrm{E}\left[\mathrm{E}\left(Q \mid Y^{o b s}, Y^{m i s}\right) \mid Y^{o b s}\right], \tag{3.6}
\end{equation*}
$$

which can be approximated by equation (3.1), considering that the values $\widehat{\theta}_{i}$ are drawn from $\mathrm{P}\left(\theta \mid Y^{o b s}, Y^{\text {mis }}\right)$. Similarly, taking into account that the posterior variance can be written as

$$
\begin{equation*}
\operatorname{Var}\left(\theta \mid Y^{o b s}\right)=\mathrm{E}\left[\operatorname{Var}\left(Q \mid Y^{o b s}, Y^{m i s}\right) \mid Y^{o b s}\right]+\operatorname{Var}\left[\mathrm{E}\left(Q \mid Y^{o b s}, Y^{m i s}\right) \mid Y^{o b s}\right] \tag{3.7}
\end{equation*}
$$

The first term in the sum is the average of the variances from the complete data pos-
terior $\widehat{\Sigma}_{i}$ which is estimated by $\widehat{W}$. The second component is the variance of the $\widehat{\theta}_{i}$ values and is approximated by $\widehat{B}$. The extra term $\widehat{B} / M$ in the MI variance estimator in equation (3.2) was introduced by Rubin (1987) and follows from the fact that $\widehat{\theta}_{M I}$ is by itself an estimate for finite $M$.

### 3.2 Validity of the MI estimator

Let's assume that a complete data procedure exists and that it yields estimators $\widehat{\theta}$ and $\widehat{\Sigma}$ of the parameter $\theta$ and its covariance matrix $\Sigma$, for example equations (2.2) and (2.3). The estimators are said to be statistically valid if

$$
\begin{equation*}
\mathrm{E}(\widehat{\theta} \mid Y) \simeq \theta, \tag{3.8}
\end{equation*}
$$

and

$$
\begin{equation*}
\mathrm{E}(\widehat{\Sigma} \mid Y) \simeq \operatorname{Var}(\widehat{\theta} \mid Y) \tag{3.9}
\end{equation*}
$$

The objective of the MI approach according to Rubin (1996) is to provide procedures that lead to statistically valid results when applied to incomplete data sets, given appropriate imputation and analysis models.

If we have an incomplete data set, it's necessary to consider an extra analysis level where the MI method is applied. In principle, the idea is to go from the incomplete data set to a complete sample and then estimate the population parameters. That means, for example, that $\widehat{\theta}$ is not only an estimator for $\theta$ but an estimand for $\widehat{\theta}_{M I}$. Rubin (1987) defines the concept of "proper imputation" (see also, Rubin, 1996) which imposes conditions on the imputation procedure that leads to valid estimators $\widehat{\theta}_{M I}$ and $\widehat{\Sigma}_{M I}$. An imputation procedure is said to be proper if

$$
\begin{align*}
& \mathrm{E}\left(\widehat{\theta}_{M I, \infty} \mid Y^{o b s}, Y^{m i s}\right)=\mathrm{E}\left(\lim _{M \rightarrow \infty} \sum_{i=1}^{M} \widehat{\theta}_{i} \mid Y^{o b s}, Y^{m i s}\right) \simeq \widehat{\theta},  \tag{3.10}\\
& \mathrm{E}\left(\widehat{W}_{\infty} \mid Y^{o b s}, Y^{m i s}\right)=\mathrm{E}\left(\lim _{M \rightarrow \infty} \sum_{i=1}^{M} \widehat{\Sigma}_{i} \mid Y^{o b s}, Y^{m i s}\right) \simeq \widehat{\Sigma}, \tag{3.11}
\end{align*}
$$

and

$$
\begin{align*}
\mathrm{E}\left(\widehat{B}_{\infty} \mid Y^{o b s}, Y^{m i s}\right) & =\mathrm{E}\left(\left.\lim _{m \rightarrow \infty} \frac{1}{M-1} \sum_{i=1}^{M}\left(\widehat{\theta}_{i}-\widehat{\theta}_{M I}\right)\left(\widehat{\theta}_{i}-\widehat{\theta}_{M I}\right)^{T} \right\rvert\, Y^{o b s}, Y^{m i s}\right) \\
& =\operatorname{Var}\left(\widehat{\theta}_{M I, \infty} \mid Y^{o b s}, Y^{m i s}\right) \tag{3.12}
\end{align*}
$$

The main result derived from the previous equations is that: if an imputation
method is proper for the parameters $\widehat{\theta}$ and $\widehat{\Sigma}$ and a complete data procedure based on such parameters is valid for $\theta$ then the inference based on MI estimators for large $M$ is also valid (Rubin, 1996).

Using equations (3.8) to (3.12) and with the help of the law of iterated expectations it follows that

$$
\begin{equation*}
\mathrm{E}\left(\widehat{\theta}_{M I, \infty} \mid Y\right)=\mathrm{E}\left[\mathrm{E}\left(\widehat{\theta}_{M I, \infty} \mid Y\right) \mid Y\right] \simeq \mathrm{E}(\widehat{\theta} \mid Y) \simeq \theta \tag{3.13}
\end{equation*}
$$

and

$$
\begin{align*}
\mathrm{E}\left(\widehat{\Sigma}_{M I, \infty} \mid Y\right) & =\mathrm{E}\left(\widehat{W}_{\infty} \mid Y\right)+\mathrm{E}\left(\widehat{B}_{\infty} \mid Y\right) \\
& =\mathrm{E}\left[\mathrm{E}\left(\widehat{W}_{\infty} \mid Y\right) \mid Y\right]+\mathrm{E}\left[\mathrm{E}\left(\widehat{B}_{\infty} \mid Y\right) \mid Y\right] \\
& \simeq \mathrm{E}(\widehat{\Sigma} \mid Y)+\mathrm{E}\left[\operatorname{Var}\left(\widehat{\theta}_{M I, \infty} \mid Y\right) \mid Y\right] \\
& \simeq \operatorname{Var}(\widehat{\theta} \mid Y)+\mathrm{E}\left(\operatorname{Var}\left(\widehat{\theta}_{M I, \infty} \mid Y\right) \mid Y\right) \\
& \simeq \operatorname{Var}\left(\mathrm{E}\left(\widehat{\theta}_{M I, \infty} \mid Y\right) \mid Y\right)+\mathrm{E}\left(\operatorname{Var}\left(\widehat{\theta}_{M I, \infty} \mid Y\right) \mid Y\right) \\
& =\operatorname{Var}\left(\widehat{\theta}_{M I, \infty} \mid Y\right) \tag{3.14}
\end{align*}
$$

where $Y=\left(Y^{\text {mis }}, Y^{\text {obs }}\right)$ is the collection of completed data sets. This shows the validity of the MI based estimators, as long as the assumptions are correct. Obtaining a valid complete data procedure is usually not a problem in most applications since common solutions use a OLS estimator. However, having an imputation that is always proper is not guaranteed. Rubin (1996) suggests that a reasonable imputation method that satisfies equation (3.12) would tend to satisfy equations (3.10) and (3.11).

On the other hand, Nielsen (2003) argues that the use of Bayesian or approximately Bayesian predictive distributions to generate imputations is inefficient even if the method is proper. Meng and Romero (2003) and Rubin (2003) discussed that issue reasoning that the relationship between the complete data procedure and the imputation method can not be overlooked. In the critical examples of Nielsen (2003) the relationship between the analysis and imputation models was ignored.

A simpler explanation is that there must be some connection between the analysis and imputation models. They can be fitted separately and to some extent, considered independently from each other, but they are not. The concept of "congeniality", introduced by Meng (1994), establishes the required relationship between analysis procedure and imputation method.

Let $\mathscr{P}_{\text {com }}=(\widehat{\theta}, \widehat{\Sigma})$ denote the complete data procedure, i.e., the statistical procedure that applied to the complete data set estimates the population parameter $\theta$ and its associated variance. Analogously, $\mathscr{P}_{\text {obs }}=\left(\widehat{\theta}_{\text {obs }}, \widehat{\Sigma}_{\text {obs }}\right)$ denotes an analysis procedure based only on the observed data. According to Meng (1994) a Bayesian model $f$ is
said to be congenial to the analysis models $\left\{\mathscr{P}_{\text {com }}, \mathscr{P}_{\text {obs }}\right\}$ for a given observed data set if:
(i) Given the completed data set, $Y=\left(Y^{o b s}, Y^{m i s}\right)$, the analysis model $\mathscr{P}_{\text {com }}$ asymptotically gives the same mean and variance estimates as the posterior mean and variance under $f$, for all possible values of $Y^{m i s}$, i.e.

$$
\begin{equation*}
\left[\mathrm{E}_{f}(\widehat{\theta} \mid Y), \operatorname{Var}_{f}(\widehat{\theta} \mid Y)\right] \simeq(\widehat{\theta}, \widehat{\Sigma}) \quad \forall Y^{m i s} \tag{3.15}
\end{equation*}
$$

(ii) The posterior mean and variance of $\theta$ under $f$ given the incomplete data are asymptotically the same as the estimate and variance from the partially observed data model $\mathscr{\mathscr { P }}_{\text {obs }}$, i.e.

$$
\begin{equation*}
\left[\mathrm{E}_{f}\left(\widehat{\theta} \mid Y^{o b s}\right), \operatorname{Var}_{f}\left(\widehat{\theta} \mid Y^{o b s}\right)\right] \simeq\left(\widehat{\theta}_{o b s}, \widehat{\Sigma}_{o b s}\right) \tag{3.16}
\end{equation*}
$$

Then the analysis procedure $\left\{\mathscr{P}_{\text {com }}, \mathscr{P}_{\text {obs }}\right\}$ is said to be"congenial" to the imputation model $g\left(Y^{\text {mis }} \mid Y^{o b s}, A\right)$ if there is a Bayesian model $f$ that (i) is congenial to $\left\{\mathscr{P}_{\text {com }}, \mathscr{P}_{\text {obs }}\right\}$ and (ii) the conditional posterior density for $Y^{\text {mis }}$ under $f$ is identical to the imputation model

$$
\begin{equation*}
f\left(Y^{m i s} \mid Y^{o b s}\right)=g\left(Y^{m i s} \mid Y^{o b s}, A\right) \quad \forall Y^{m i s}, \tag{3.17}
\end{equation*}
$$

where $A$ represents possible additional data used in the imputation. This definition establishes sufficient conditions to obtain proper valid results. If the analysis procedure is congenial to the imputation model, the MI estimators are valid.

Nielsen (2003) showed that a necessary and sufficient condition for an analysis procedure to be congenial to an imputation procedure is that the complete data and observed data estimators are maximum likelihood efficient and their matching variance estimators are equal to the inverse Fisher information. These results imply that the congeniality assumption does not hold for some simple estimators, for example, OLS for heteroscedastic errors. Other cases of uncongeniality can be given when different variables are used in the imputation as those used in the analysis of the scientific model of interest. Alternative, although computationally more complex variance estimators were proposed by Robins and Wang (2000) and Yang and Kim (2016, Theorem $2)$.

### 3.3 Frequentist Inference

Given certain regularity conditions in a congenial setting, MI approximates a full Bayesian analysis (Carpenter and Kenward, 2012). Since in some fields of applica-
tions a frequentist approach is more desirable, we will discuss how to perform frequentist inference on $\theta$, i.e., how to obtain valid estimations of the variance, sampling distribution and confidence intervals. For a more extensive presentation Chapter 4 of Rubin (1987) is recommended.

We want to estimate a uni-dimensional parameter $\theta$ in our model of interest (2.1). Let's assume that the imputation and analysis models are congenial. Applying the procedure explained in section 3.1 we create $M$ imputed data sets $\left\{\widetilde{Y}_{m}^{m i s}, Y^{o b s}\right\}, m=$ $1, \ldots, M$ using the conditional predictive distribution $f\left(Y^{m i s} \mid Y^{o b s}, R\right)$ and then use those data sets to solve the estimating equation in the analysis model to obtain $\widehat{\theta_{m}}$ and $\widehat{\sigma}_{m}$.

In a first scenario, let's assume that the number of imputations $M$ is infinite. Then, by virtue of equations (3.13) and (3.14), $\widehat{\theta}_{M I, \infty}$ is a consistent estimator of $\theta$ and

$$
\begin{equation*}
\operatorname{Var}\left(\widehat{\theta}_{M I, \infty}\right)=\widehat{W}_{\infty}+\widehat{B}_{\infty} \tag{3.18}
\end{equation*}
$$

as defined in equations (3.3) and (3.4). If the sample size is large enough such that $\widehat{\theta}$ is normally distributed if the data were fully observed, the Bayesian posterior of $\theta$ from a frequentist perspective gives

$$
\begin{equation*}
\theta \sim N\left(\widehat{\theta}_{M I, \infty}, \widehat{W}_{\infty}+\widehat{B}_{\infty}\right) \tag{3.19}
\end{equation*}
$$

Therefore a $100(1-\alpha) \%$ confidence interval can be constructed as

$$
\begin{equation*}
\left(\widehat{\theta}_{M I, \infty}-z_{1-\alpha / 2} \sqrt{\widehat{\Sigma}_{M I, \infty}}, \widehat{\theta}_{M I, \infty}+z_{1-\alpha / 2} \sqrt{\widehat{\Sigma}_{M I, \infty}}\right) \tag{3.20}
\end{equation*}
$$

### 3.3.1 Finite Imputations

Let's assume now that the sample size is still large but the number of imputations $M$ is finite, then the normal approximation given by equation (3.19) may not be appropriate. Let $S_{M}$ denote the finite set of complete data statistics $\left\{\widehat{\theta}_{m}, \widehat{\Sigma}_{m}\right\}$. The objective is to approximate the conditional distribution of $\theta$ given $S_{M}$. This idea is developed with rigor in Rubin, 1987, Section 3.3.

Using the fact that $S_{M}$ is an i.i.d. sample from the posterior mean and variance of $\theta$, weak regularity conditions and using asymptotic theory it can be shown that the distribution of $\widehat{\theta}_{M I, \infty}$ and $\widehat{W}_{\infty}$ conditional on $S_{M}$ and $\widehat{B}_{\infty}$

$$
\begin{align*}
\left(\widehat{\theta}_{M I, \infty} \mid S_{M}, \widehat{B}_{\infty}\right) & \sim N\left(\widehat{\theta}_{M I}, \widehat{B}_{\infty} / M\right)  \tag{3.21}\\
\left(\widehat{W}_{\infty} \mid S_{M}, \widehat{B}_{\infty}\right) & \sim\left(\widehat{W}^{2} \ll \widehat{B}_{\infty} / M\right) \tag{3.22}
\end{align*}
$$

where, as per Rubin, 1987, Section 2.10, $A \sim(B, \ll C)$ means that the distribution of $A$ tends to be centered at $B$ with each component having variability substantially less than each positive component of $C$. Combining equations (3.21) and (3.22) with (3.19) we obtain

$$
\begin{equation*}
\theta \sim N\left(\widehat{\theta}_{M I}, \widehat{W}+\left(1+M^{-1}\right) \widehat{B}_{\infty}\right) \tag{3.23}
\end{equation*}
$$

Using Cochran's theorem (Cochran, 1934) and by virtue of equation (3.21), the distribution of $\widehat{B}_{\infty}$ conditional on $S_{M}$ is proportional to an inverted $\chi^{2}$ random variable with $M-1$ degrees of freedom, that is:

$$
\begin{equation*}
\left(\left.(M-1) \frac{\widehat{B}}{\widehat{B}_{\infty}} \right\rvert\, S_{M}\right) \sim \chi_{M-1}^{2} . \tag{3.24}
\end{equation*}
$$

Then given $S_{M}$, the variance in equation (3.23) is the sum of an inverted $\chi^{2}$ and a constant. That implies that the distribution of $\theta$ given $S_{M}$ follows a Fisher-Behrens distribution. Nevertheless Rubin (1987) provides an approximation of the conditional distribution of the variance to an inverted $\chi^{2}$, and then formulates the related $t$ distribution. Specifically, the proposed approximation is:

$$
\begin{equation*}
\left(\left.v \frac{\widehat{W}+\left(1+M^{-1}\right) \widehat{B}}{\widehat{W}+\left(1+M^{-1}\right) \widehat{B}_{\infty}} \right\rvert\, S_{M}\right) \sim \chi_{v}^{2} \tag{3.25}
\end{equation*}
$$

being the numerator estimator of the variance, $\widehat{\Sigma}_{M I}$ as it was defined in equation (3.2), and $v$ the degrees of freedom

$$
\begin{equation*}
v=(M-1)\left(1+r_{M}^{-1}\right)^{2}, \tag{3.26}
\end{equation*}
$$

where

$$
\begin{equation*}
r_{M}=\frac{\left(1+M^{-1}\right) B}{W} \tag{3.27}
\end{equation*}
$$

represents the relative increase in conditional variance due to the missing data (see Rubin, 1987).

The use of Rubin's approximation and its variance estimator in equation (3.23) allows to perform statistical inference about $\theta$ using a $t$ distribution with $v$ degrees of freedom. For example, a $100(1-\alpha) \%$ confidence interval can be constructed as

$$
\begin{equation*}
\left(\widehat{\theta}_{M I}-t_{v}(1-\alpha / 2) \sqrt{\widehat{\Sigma}_{M I}}, \widehat{\theta}_{M I}+t_{v}(1-\alpha / 2) \sqrt{\widehat{\Sigma}_{M I}}\right) \tag{3.28}
\end{equation*}
$$

If $\theta$ is a $p$-dimensional vector, Li, Raghunathan, and Rubin (1991) propose to base
the tests on the approximation:

$$
\begin{equation*}
\frac{\left(\widehat{\theta}_{M I}-\theta\right)^{T} \widehat{\Sigma}_{M I}^{-1}\left(\widehat{\theta}_{M I}-\theta\right)}{p(1+r)} \sim F_{p, v^{\prime}}, \tag{3.29}
\end{equation*}
$$

where

$$
r=\frac{1}{p}\left(1+\frac{1}{M}\right) \operatorname{tr}\left(\widehat{B} \widehat{W}^{-1}\right),
$$

and

$$
v^{\prime}= \begin{cases}4+(t-4)\left(1+\left(1-2 t^{-1}\right) / r\right)^{2} & \text { if } t=p(M-1)>4 \\ t\left(1+p^{-1}\right)\left(1+r^{-1}\right)^{2} / 2 & \text { otherwise }\end{cases}
$$

In the case of a small sample size, where the complete data statistic is already $t$ distributed, Barnard and Rubin (1999) discuss how to adjust the degrees of freedom.

### 3.4 Number of Imputations

It has been shown that multiple imputations can yield valid inference, even for values of $M$ between 3 and 5 (Carpenter and Kenward, 2012; van Buuren, 2012). This practice is justified analyzing the loss of relative efficiency when using a finite value of $M$ instead of infinite imputations. The relative efficiency is, approximately

$$
\begin{equation*}
\widehat{\Sigma}_{M I}=\left(1+\frac{\gamma}{M}\right) \widehat{\Sigma}_{M I, \infty}, \tag{3.30}
\end{equation*}
$$

where

$$
\begin{equation*}
\gamma=\frac{r_{M}+2 /(v+3)}{r_{M}+1} \tag{3.31}
\end{equation*}
$$

is the estimated fraction of missing information, with $v$ and $r_{M}$ given by equations (3.26) and (3.27) (Rubin, 1987). For example, if the fraction of missing information is 0.3 and $M$ is set to 5 , the estimated variance $\widehat{\Sigma}_{M I}$ will be only 1.06 times larger than $\widehat{\Sigma}_{M I, \infty}$ yielding a confidence interval just $\sqrt{1.06}=1.03$ times longer than ideal.

The problem with this argument is that, while it is valid in the estimation of $\theta$, it doesn't work the same way when estimating $p$-values (Carpenter and Kenward, 2012). Graham, Olchowski, and Gilreath (2007) did a simulation study investigating the effect of $M$ on the statistical power of a test for detecting an effect size of less than 0.1. They found that in order to be closer than $1 \%$ of the theoretical power and for fractions of missing information varying from 0.1 to 0.9 , the number of imputations $M$ must range from 20 to values larger than 100.

Van Buuren (2012) suggests to use a small number of imputations when doing an exploratory analysis to build the imputation model, and increase $M$ when doing the
final analysis.

### 3.5 Multivariate Missing Data

Real-world data sets with missing values will often have more than one incompletely observed variable. So far, this chapter has focused on the justification and inferential aspects of the MI estimator without considerations on how to select and specify the imputation model. The following sections define the two main approaches available: Joint Modeling (JM) and Fully Conditional Specification (FCS).

### 3.5.1 Joint Modeling

Joint Modeling supposes that the data can be described by a multivariate distribution and assuming ignorability, imputations are created by drawing from said fitted distribution. Common imputation models are based on the multivariate normal distribution (Schafer, 1997). For simplicity, let's assume that

$$
\begin{equation*}
Y \sim N(\mu, \Sigma) \tag{3.32}
\end{equation*}
$$

where $\mu=\left(\mu_{1}, \ldots, \mu_{p}\right)$ and $\Sigma$ a $p \times p$ covariance matrix. Taking a flat prior distribution for $\mu$ and a $W_{p}\left(v, S_{p}\right)$ prior for $\Sigma^{-1}$, if $Y$ were fully observed, the posterior distribution of $(\mu, \Sigma)$ given $Y$ could be written as the product of

$$
\begin{equation*}
\mu \mid Y, \Sigma \sim N\left(\bar{Y}, n^{-1} \Sigma\right) \tag{3.33}
\end{equation*}
$$

and

$$
\begin{equation*}
\Sigma^{-1} \mid Y \sim W_{p}\left(n+v,\left(S_{p}^{-1}+S\right)^{-1}\right) \tag{3.34}
\end{equation*}
$$

where $\bar{Y}$ and $(n-1)^{-1} S$ are the sample mean and covariance matrix respectively (Carpenter and Kenward, 2012, Appendix B).

If $Y$ is incompletely observed, the estimation of equations (3.33) and (3.34) can be achieved with the use of the Gibbs sampler as described in algorithm 1. The procedure will draw parameters in an alternate fashion, conditional on all others and the data. In the first step the missing data is commonly initialized with a bootstrap sample of the observed data. After the sampler reached its stationary distribution, multiple imputations can be generated by taking $Y_{\star}^{\text {mis }}$ draws sufficiently spaced from each other. The " $\star$ " symbol denotes that the variable or parameter is a random draw from a posterior

```
Algorithm 1 Joint Modeling Gibbs Sampler
    Fill in missing data \(Y^{\text {mis }}\) bootstrapping the observed data \(Y^{\text {obs }}\)
    Estimate \(\bar{Y}\) and \(S\)
    Draw \(\Sigma_{\star}^{-1}\) and \(\mu_{\star}\) using equations (3.34) and (3.33)
    Draw \(Y_{\star}^{\text {mis }} \sim N\left(\mu_{\star}, \Sigma_{\star}\right)\)
    Update the estimation of \(\bar{Y}\) and \(S\)
    Repeat steps 3 to 5 a large number of times to allow the sampler to reach its
    stationary distribution.
```

conditional distribution.
This methodology is attractive if the multivariate distribution is a good model for the data but may lack the flexibility needed to represent complex data sets encountered in real applications. In such cases, the joint modeling approach is difficult to implement because the typical specifications of multivariate distributions are not sufficiently flexible to accommodate these features (He and Raghunathan, 2009). Also, most of the existing model-based methods and software implementations assume that the data originate from a multivariate normal distribution (e.g., Honaker, King, and Blackwell, 2011; Templ, Kowarik, and Filzmoser, 2011; van Buuren, 2007).

Demirtas, Freels, and Yucel (2008) showed in a simulation study, that imputations generated with the multivariate normal model can yield correct estimates, even in the presence of non-normal data. Nevertheless, the assumption of normality is inappropriate as soon as there are outliers in the data, or in the case of skewed, heavy-tailed or multimodal distributions, potentially leading to deficient results (He and Raghunathan, 2009; van Buuren, 2012). To generate imputations when variables in the data set are binary or categorical, latent normal model (Albert and Chib, 1993) or the general location model (Little and Rubin, 2002) are also alternatives.

### 3.5.2 Fully Conditional Specification

Sometimes the assumption of a joint distribution on the data can not be justified, especially with a complex data set consisting of a mix of several different continuous and categorical variables. An alternative multivariate approach is given by the Fully Conditional Specification. The method requires the specification of an imputation model for each incompletely observed variable and impute values iteratively one variable at a time. This is one of the great advantages of this method, since it decomposes a high dimensional imputation model into one-dimensional problems, making it a generalization of univariate imputation (van Buuren, 2012).

This method is most commonly applied through the Multivariate Imputation by Chained Equations (MICE) algorithm (van Buuren and Groothuis-Oudshoorn, 2011).

This method is summarized in algorithm 2. For each variable with missings a density, $f_{j}\left(Y_{j} \mid Y_{j-}, \Theta_{j}\right)$, conditional on all other variables is specified, where $\Theta_{j}$ are the imputation model parameters. MICE, essentially a MCMC method, visits sequentially each variable with missings and draws alternately the imputation parameters and the imputed values.

```
Algorithm 2 MICE (FCS)
    Fill in missing data \(Y^{\text {mis }}\) bootstrapping the observed data \(Y^{\text {obs }}\)
    For \(j=1, \ldots, p\)
        a. Draw \(\Theta_{j}^{\star}\), from the posterior distribution of the imputation parameters.
        b. Impute \(Y_{j}^{\star}\) from the conditional model \(f_{j}\left(Y_{j} \mid Y_{j^{-}}, \Theta_{j}^{\star}\right)\)
    Repeat step \(2 K\) times to allow the Markov chain to reach its stationary distribution.
```

The FCS approach splits high-dimensional imputation models into multiple onedimensional problems and is appealing as an alternative to joint modeling in cases where a proper multivariate distribution can not be found or when it does not exist. The choice of imputation models in this setting can be varied, for example, parametric models like the Bayesian linear regression, logistic regression, logit or multilevel models. Liu et al. (2013) studied the asymptotic properties of this iterative imputation procedure and provided sufficient conditions under which the imputation distribution converges to the posterior distribution of a joint model.
van Buuren (2012) claims that, in practice, $K$ in step 3 of algorithm 2 can be set to a value between 5 and 20. This is a strong claim, since usual applications of MCMC methods require a large number of iterations. The justification is based on the fact that the random variability introduced by using imputed data in step 2, will reduce the autocorrelation between iterations in the Markov Chain, speeding up the convergence.

### 3.5.3 Compatibility

To discuss the validity of the FCS approach it is necessary to define the term "compatibility" first. A set of density functions, $\left\{f_{1}, \ldots, f_{j}\right\}$, is said to be compatible if there is a joint distribution $f$ that generates such set.

The same flexibility of MICE that allows for very special conditional distributions and imputation models has as a drawback the fact that the joint distribution is not explicitly known, and there is the possibility that it doesn't even exists. This is the case if the conditional distributions specified are incompatible.

Incompatibility in MICE can be the result of imputing deterministic functions of
variables in the data along with those same original variables. For example, there could be interaction terms or nonlinear functions of the data in the imputation models, introducing feedback loops and impossible combination in the algorithm which would lead to invalid imputations (van Buuren and Groothuis-Oudshoorn, 2011). For that reason, the discussion about the congeniality of the imputation and substantive models is replaced by an analysis of their compatibility.

Although FCS is only justified to work if the conditional models are compatible, Buuren et al. (2006) reports a simulation study with models with strong incompatibilities where the estimates after performing multiple imputation were still acceptable.

## Chapter 4

## Imputation Methods

Van Buuren (Appendix A, 2012) contains an overview of available MI libraries for programming languages and statistical software like R, SPSS, SAS, S-Plus and Stata. Salfran and Spiess (2015) described some of the most common imputation methods included in these software packages. This chapter provides more details about the imputing algorithms, incorporating also the methods that will be used later in Chapter 6 in the simulation experiment.

Section 4.1 illustrates the Bayesian Linear regression, one of the older and most popular methods. Section 4.2 describes Amelia a method published in 2010. Section 4.3 outlines algorithms in the family of Hot Deck imputation methods, like the PMM approach. Section 4.4 depicts a rather new method based on the software IVEware. Section 4.5 present a class of imputation methods based on recursive partitioning.

### 4.1 Bayesian Linear Regression

Imputation by parametric Bayesian regression models is one of the most common methods of imputation for an univariate variable, $Y_{j}$, with missing values (Rubin, 1987, see Examples 5.1 and 5.3). It is implemented in practically all imputation software packages. It assumes that the posterior density of $Y_{j}, f\left(Y_{j} \mid \omega, \eta\right)$, can be specified as

$$
\begin{equation*}
Y_{j} \sim N\left(\omega \beta, \sigma^{2}\right) \quad \sigma>0, \tag{4.1}
\end{equation*}
$$

where $\omega=\left(1, Y_{j^{-}}\right), \eta=(\beta, \log (\sigma)), \beta$ is a vector of $j$ components and $\sigma$ is a scalar. If the prior density of $\eta$ is proportional to a constant and the missing values are MAR the imputation procedure is given by algorithm 3

Using the theory of generalized linear models (GLM, McCullagh and Nelder, 1989) the Bayesian Linear Regression model can be also extended through a link function

## Algorithm 3 Bayesian Linear Regression - Part 1

: Estimate $\widehat{\beta}$ from the model $Y_{j}=\omega \beta+\epsilon$ using the observed data.
2: Draw $\mathscr{X}^{2}$, a $\chi_{n_{\text {oss }}-j}^{2}$ random variable and let

$$
\sigma_{\star}^{2}=\sum_{n_{\mathrm{obs}}}\left(Y_{i j}-\omega_{i} \widehat{\beta}\right)^{2} / \mathscr{X}^{2} .
$$

3: Draw $Z$, a $N(0,1)$ random variable and let

$$
\beta_{\star}=\widehat{\beta}+\sigma_{\star}\left(\sum_{n_{\text {obs }}}\left[\omega_{i} / \omega_{i}\right]\right)^{-1 / 2} Z
$$

where $\left(\sum_{n_{\text {obs }}}\left[\omega_{i} / \omega_{i}\right]\right)^{-1 / 2}$ is the triangular square root obtained by the Cholesky factorization of $\sum_{n_{\text {obs }}}\left[\omega_{i} / \omega_{i}\right]$.
4: Impute $Y_{j}^{\text {mis }}$ as

$$
Y_{i j}^{\star}=\omega_{i} \beta_{\star}+\xi_{i} \sigma_{\star}
$$

where $\xi_{i}$ are independently drawn from a standard normal distribution.
: Repeat steps 2 to $4 M$ times to generate multiple imputations.
$g(\cdot)$ such as:

$$
\begin{align*}
\mathrm{E}\left(Y_{j} \mid \omega\right) & =g^{-1}(\omega \beta)  \tag{4.2}\\
\operatorname{Var}\left(Y_{j} \mid \omega\right) & =v\left(g^{-1}(\omega \beta)\right) \tag{4.3}
\end{align*}
$$

where $v$ is a skedastic function of the mean.
In case that $g(x)=x$ and $v(x)=\sigma^{2}$, the GLM model is simplified to the linear regression model in equation (4.1). If for example $Y_{j}$ is a binary variable, then using a logit link function such as $\mathrm{E}\left(Y_{j} \mid \omega\right)=\operatorname{logit}^{-1}(\omega \beta)$ equation (4.1) turns into:

$$
\begin{equation*}
Y_{j} \sim \operatorname{Bernoulli}(p), \tag{4.4}
\end{equation*}
$$

where $p=\operatorname{logit}{ }^{-1}(\omega \beta)$. The imputation algorithm is the same as algorithm 3 except the actual imputation step, where $Y_{i j}^{\star}$ is a draw from a Bernoulli distribution with parameter $p_{i}^{\star}=\operatorname{logit}^{-1}\left(\omega_{i} \beta_{\star}\right)$.

This imputation procedure is justified by Rubin (1987) and may be expected to allow valid inferences not only if the assumptions underlying the imputation models are correct but, due to the "self-correcting" property of MI Little and Rubin (2002) and Rubin (1987, 1996, 2003), to a certain extent even in more general situations, like non-linear or non-normal models in the case of continuous $Y_{j}$ or misspecified mean models in the binary case.

### 4.2 Amelia

Honaker, King, and Blackwell (2011) propose a joint modeling approach in the form of an imputation method called 'Amelia II'.

Amelia assumes a normal multivariate distribution for the variables in the data set, i.e., $Y \sim N(\theta, \Sigma)$. The method avoids drawing from the posterior distribution of the parameters, as in step 2 and 3 from algorithm 3 by combining the bootstrap (Efron, 1979) with the EM algorithm (Dempster, Laird, and Rubin, 1977). The imputation method is briefly described by algorithm 4 . For more details on the expectationmaximization with bootstrapping (EMB) algorithm see Honaker and King (2010).

```
Algorithm 4 EMB imputation (Amelia)
    Bootstrap \(M\) incomplete data sets.
    Estimate vector \(\widehat{\mu_{i}}\) and matrix \(\widehat{\Sigma_{i}}, i=1, \ldots, M\), using the EM algorithm
    Produce \(M\) imputed data sets drawing from \(N\left(\widehat{\mu}_{i}, \widehat{\Sigma}_{i}\right), i=1, \ldots, M\).
```

This imputation algorithm is provided by the R package Amelia. If the variable $Y_{j}$ to be imputed is non-normal, Honaker, King, and Blackwell (2011) suggest to transform the data to make it look closer to a normally distributed variable. In particular, if $Y_{j}$ is nominal variable, they propose to impute them as if it were continuous, scale it into probabilities and draw values for the multinomial distribution using these probabilities.

### 4.3 Hot Deck Imputation

Hot deck imputation is an alternative to fully parametric methods, which consists of replacing the missing value with the response of a "similar" observed variable. One common class of hot deck methods is constituted by $k$-nearest neighbor ( $k N N$ ) techniques with advantages that have been discussed by Andridge and Little (2010), Little (1988), and Schenker and Taylor (1996). The method is simple, it seems to avoid strong parametric assumptions, only eligible and observed values are imputed, and it can easily be applied to various types of variables to be imputed.

The idea is to find, for each missing value $Y_{i j}, k$ completely observed neighbors, somehow close with respect to $Y_{i j^{-}}$. From this pool of neighbors, one donor is randomly selected and its value $Y_{i j}^{\star}$ is taken as an imputation for $Y_{i j}$. Closeness is usually expressed as a distance measure, one popular being based on the estimated condi-
tional mean of $Y_{j} \mid Y_{j^{-}}$,

$$
\begin{equation*}
d_{i, i^{\prime}}=\left|\widehat{\mathrm{E}}\left(Y_{i j}^{\mathrm{mis}} \mid Y_{i j^{-}}\right)-\widehat{\mathrm{E}}\left(Y_{i^{\prime} j}^{\mathrm{obs}} \mid Y_{i^{\prime} j^{\prime}}\right)\right|, \tag{4.5}
\end{equation*}
$$

where $Y_{i j}^{\text {mis }}$ denotes case $i$ of variable $Y_{j}$ whose value has not been observed, and $Y_{i^{\prime} j}^{\text {obs }}$ denotes case $i^{\prime}$ of variable $Y_{j}$ whose value has been observed ( $i, i^{\prime}=1, \ldots, n$ ).

### 4.3.1 Predictive Mean Matching

When the linear predictor of the regression of $Y_{j}$ on $\omega=\left(1, Y_{j^{-}}\right)$is used for the distance in equation (4.5), the imputation technique is also called "predictive mean matching" (PMM) imputation and goes back to Rubin $(1986,1987)$ and Little $(1988)$ who coined the name. The distance function transforms into:

$$
\begin{equation*}
d_{i, i^{\prime}}^{P M M}=\left|\left(\omega_{i}-\omega_{i^{\prime}}\right)^{\prime} \beta^{\star}\right| \tag{4.6}
\end{equation*}
$$

where $\beta^{\star}$ is a random draw from the posterior distribution $\beta$ in the standard linear regression model $Y_{j}=\omega \beta$. Since the matching is based on the linear predictor and only observed values are imputed, the method can also be applied to impute noncontinuous variables, e.g., binary variables (van Buuren and Groothuis-Oudshoorn, 2011). Algorithm 5 describes the imputation method.

```
Algorithm 5 Predictive Mean Matching
    Draw parameter \(\beta^{\star}\) from its posterior distribution using steps 1 to 3 of algorithm
    3.
    For each missing case \(i\) in variable \(Y_{j}\)
            a. Calculate \(d_{i, i^{\prime}}^{P M M}\) for each observed case \(i^{\prime}\) of variable \(Y_{j}\).
            b. Sort the distances and create a set (donor pool) of the first \(k\) observed values
            \(Y_{i^{\prime} j}\) with smallest \(d_{i, i^{\prime}}^{P M M}\).
            c. Select \(Y_{i^{\prime} j}^{\star}\) at random from the donor pool.
            d. Impute \(Y_{i j}^{\star}=Y_{i^{\prime} j}^{\star}\)
    : Repeat steps 1 and \(2 M\) times to generate multiple imputations.
```

Under the assumptions that the distance function in equation (4.5) is topologically equivalent to the Euclidean distance and that $k=n^{r}$ with $r \in(0,1)$ as the sample size $n \rightarrow \infty$, Dahl (2007) shows that imputations based on $k N N$ techniques can be interpreted as draws from the conditional distribution of the incompletely observed
variable given observed values, that is:

$$
\left(Y_{j}^{\star} \mid Y_{j^{-}}^{m i s}, Y_{j}^{\mathrm{obs}}\right) \xrightarrow[n \rightarrow \infty]{\mathscr{D}}\left(Y_{j}^{\mathrm{mis}} \mid Y_{j^{-}}^{\mathrm{mis}}, Y_{j}^{\mathrm{obs}}\right)
$$

with bounded correlations

$$
\left|\rho\left(Y_{j}^{\star}, f\left(Y_{j^{-}}, Y_{j}^{o b s}\right)\right)\right| \leq n^{1 / 4},
$$

where $f$ is any measurable function. This means that if the assumptions are true, the given $k N N$ method will produce imputations with the correct conditional distribution and they will be asymptotically independent over observations. Dahl (2007) proposes $k(n)=\sqrt{n}$ as this is 'canonical in the sense of representing the mid-point of the interval' defined by $r \in(0,1)$ (Dahl, 2007, p. 5915).

Convergence rates to the true distribution may vary at different query points, depending on whether regions are thinned out by the response mechanism or not, which is not the case if the missing data are MCAR, as in the simulation study of Schenker and Taylor (1996). In addition, mostly all imputation software implementation of the $k N N$ method provides PMM with $k$ being a parameter that is set to be constant violating the second assumption. Further, $d_{i, i^{\prime}}^{P M M}$ is not Euclidean, since it can be zero even if $\omega \neq \omega^{\prime}$.

The implementation of PMM in the R package mice uses a slightly different distance measure, proposed by van Buuren and Groothuis-Oudshoorn (2011),

$$
\begin{equation*}
d_{i, i^{\prime}}^{M I C E}=\left|\omega_{i} \beta^{\star}-\omega_{i^{\prime}} \widehat{\beta}\right|, \tag{4.7}
\end{equation*}
$$

where $\widehat{\beta}$ is the posterior mean of the parameters of the imputation regression model, and $\beta^{\star}$ is a draw from the corresponding posterior distribution (Vink et al., 2014).

Two notes are worth mentioning. First, by using observed $Y_{i j}$ values from some donors as imputations, it is implicitly assumed, that they are random independent draws from an approximate posterior distribution of $Y_{j}^{\text {mis }}$ given $Y_{j^{-}}^{\text {mis }}$. Thus, the assumption is, that the probability of observing $Y_{j}$ given $Y_{j^{-}}^{\text {mis }}$ is independent of differences between $Y_{j^{-}}^{\text {mis }}$ and $Y_{j^{-}}^{\text {obs }}$, the values of $Y_{j^{-}}$of completely observed neighbors. Salfran and Spiess (2015) discussed that this is equivalent to assuming, that the missing data are MCAR within the cells implicitly defined by the $k$ neighbors. Strictly speaking, the assumption is, that the missing data are neither MCAR nor MAR, but missing locally completely at random (MLCAR).

Second, a special case of $k N N$ imputation is $k=1$, i.e. the closest neighbor is the donor. In this case, there is no random selection of the values to be imputed and even appropriately taking into account the uncertainty in the parameter estimator of the
imputation model does not make this method proper. Thus, $k$ should always be larger than one.

There has been simulation results implying that PMM versions of $k N N$ imputation seem to work well (e.g., Andridge and Little, 2010; Vink et al., 2014; Yu, Burton, and Rivero-Arias, 2007). However, it is not clear if $k N N$ imputation techniques are proper imputation methods. In fact, Schenker and Taylor (1996) state, that if the number of possible donors is too small, the $M$ imputations will be correlated leading to a higher variance of the estimator of interest. On the other hand, increasing the number of neighbors of a case to be imputed (the query point), may lead to biased estimators due to a violation of the MLCAR assumption. In a simulation study using fixed (three and ten) possible donors they found a slight under-coverage of the interesting parameter of two to three percent. The missing data in their study are MCAR. Similar results are reported from a simulation study of de Jong, van Buuren, and Spiess (2016) with missing data being MAR, who found no (obvious) bias but mild to moderate undercoverage using the $k N N$ imputation method with $k=3$.

Most standard analysis software packages or functions offer one of these or a similar $k N N$ technique, often with a default value for $k$, like $k=5$ (e.g., SAS Institute Inc., 2015; van Buuren and Groothuis-Oudshoorn, 2011).

### 4.3.2 aregImpute

Unfortunately, a distance measure based on linear regression models ignores nonlinear effects of $Y_{j^{-}}$on $Y_{j}$ and may hence still be too restrictive. Thus, a non-parametric version of $k N N$ imputation provided by function aregImpute as part of the R package Hmisc has been proposed by Harrell (2015). The suggested algorithm uses the following distance function:

$$
\begin{equation*}
d_{i, i^{\prime}}^{\text {areg }}=\sum_{l=1}^{L}\left|\left(f_{l}\left(Y_{i j^{-}}\right)-f_{l}\left(Y_{i^{\prime} j^{-}}\right)\right) \beta_{l}^{\star}\right|, \tag{4.8}
\end{equation*}
$$

where $f_{l}(\cdot), l=1, \ldots, L$ is a cubic spline basis which lead to optimal prediction, according to the coefficient of determination $R^{2}$, of a linear transformation of $Y_{j}$ in the following additive model:

$$
c+Y_{j} d=\alpha+\sum_{l=1}^{L} f_{l}\left(Y_{j^{-}}\right) \beta_{l}+v
$$

The values of $\beta_{l}^{\star}$ are obtained using a non-parametric bootstrap.
Afterwards, the imputed values are obtained exactly as described in the last part
of Algorithm 5, or optionally by randomly selecting a donor from a neighborhood of the query point with probability inversely proportional to their distance from the observation with a missing value. For a description, see Harrell (2015) and the literature cited therein.

### 4.3.3 MIDAStouch

A rather new method for $k N N$ imputation can be found in the R package midastouch (Gaffert, Meinfelder, and Bosch, 2016) which is in turn based on MIDAS, a SAS macro for multiple imputation using distance aided selection of donors (Siddique and Harel, 2009).

Gaffert, Meinfelder, and Bosch (2016) were concerned with the frequentist properties of the PMM method, specifically a systematic underestimation of the model variance. They propose a method based on the Approximate Bayesian Bootstrap which uses a new distance function in combination with bootstrap weights to construct the donor pool and select the imputed value.

The distance function used is

$$
\begin{equation*}
d_{i, i^{\prime}}^{M T}=\left|\left(\omega_{i}-\omega_{i^{\prime}}\right) \beta_{-i^{\prime}}^{\star}\right| \tag{4.9}
\end{equation*}
$$

where $\beta_{-i^{\prime}}^{\star}$ is a random draw from the posterior distribution of $\beta_{-i^{\prime}}$ as in the distance function given by equation (4.6) but following the leave-one-out principle, so $\beta_{-i^{\prime}}$ is not conditional on the observed case $i^{\prime}$.

The donor pool consists of all observed values, defining a probability for every donor of being used as the imputed value given by

$$
\begin{equation*}
\mathrm{P}\left(Y_{i j}^{\star}=Y_{i^{\prime} j}\right)=\frac{v_{i^{\prime}} d_{i, i^{\prime}}^{-k}}{\sum_{i^{\prime}=1}^{n_{o s}}\left(v_{i^{\prime}} d_{i, i^{\prime}}^{-\kappa}\right)} \tag{4.10}
\end{equation*}
$$

where $v$ denotes non-negative bootstrap weights of the donors, and $\kappa$ a "closeness" parameter adjusting the importance of the distance. For a more detailed description on how to set the bootstrap weights or other parameters, see Gaffert, Meinfelder, and Bosch (2016).

### 4.4 Iterative Robust Model-based Imputation

Templ, Kowarik, and Filzmoser (2011) propose an algorithm called 'Iterative Robust Model-based Imputation' (IRMI) implemented in the R package VIM (Alexander Kowarik and Matthias Templ, 2016). The method copies the functionality of IVEware (Raghu-
nathan et al., 2001), modifying the methodology by initializing missing values with the median and adopting one of several robust estimation methods to reduce the influence of outlying observations on the regression parameter estimates.

The essence of the method is described by algorithm 6. It can be seen that it is an imputation procedure like the Bayesian linear regression, but instead of drawing parameters from their posterior distribution or bootstrapping the observed data set, they are fixed at their posterior mean and variance. Supposedly the factor multiplying the estimated variance accounts for the additional uncertainty in the imputations due to the need of estimating the model, although no justification is given for the value of this factor.

Algorithm 6 Iterative Robust Multiple Imputation
Estimate, using a robust method, $\widehat{\beta}$ from the model $Y_{j}=\omega \beta$ using the observed data.
Impute $Y_{j}^{\text {mis }}$ as

$$
Y_{i j}^{\star}=\omega_{i} \widehat{\beta}+\sqrt{1+\frac{n_{\text {mis }}}{n}} \widehat{\sigma}
$$

where $\widehat{\sigma}$ is the robust variance estimator from the residuals in the model.
Iterate steps 1 and 2 until the imputed values stabilize, i.e., until

$$
\sum_{n_{\text {mis }}}\left(Y_{i j}^{\star, l}-Y_{i j}^{\star, l-1}\right)<\delta
$$

for a small constant $\delta$, where $Y_{i j}^{\star l}$ and $Y_{i j}^{\star, l-1}$ are the imputed values in the $l$-th and ( $l-1$ )-th iterations respectively.
Repeat steps 1 to $3 M$ times to generate multiple imputations.

The default option for continuous dependent variables in IRMI is the MM-estimator proposed by Yohai (1987), which is efficient in linear regression models with normally distributed errors but at the same time largely ignores outliers. The principal problem of such an automatic method, however, is that it does not differentiate between valid and invalid outliers. Thus, e.g., if the conditional distribution of a variable to be imputed is skewed, valid values in a sparsely populated region may be ignored when the model is fitted. This would lead to estimating the imputation model using systematically selective samples and thus to adopting an improper imputation method. The same arguments apply to the robust imputation techniques for discrete variables.

A limited simulation study presented by Templ, Kowarik, and Filzmoser (2011) is intended to show the good properties of the technique. However, coverage rates of the true values in this study range between 0.882 and 0.906 , given $\alpha=0.05$. In fact, this imputation method seems not to be proper. In an additional study, imputation tech-
niques are evaluated based on comparisons of true but unobserved and imputed values. With respect to these error measures, the technique proposed in Templ, Kowarik, and Filzmoser (2011) performs better than an imputation method using Bayesian linear regression. However, for an imputation method to be proper, it is neither required nor implied that some measure of distances between true and imputed values is minimal (see Rubin, 1987, 1996, 2003). Salfran, Jordan, and Spiess (2016) presented simulation results showing the method regularly producing larger biases and lower values of coverage than others methods. At the same time the reported mean square errors were smaller than the remaining methods.

### 4.5 Recursive Partitioning

Let's continue with the incompletely observed variable $Y_{j}$. Assume that we want to use $Y_{j}=h\left(Y_{j^{-}}\right)$, where $h$ is a model that includes interactions among the $Y_{j^{-}}$predictors. The imputation methods described so far allow the use of such a model, although it would make the matter of congeniality even harder to justify, to the point of getting uncongenial models if the scientific model of interest does not include such interactions.

An alternative approach is described by Doove, Van Buuren, and Dusseldorp (2014) who define a new class of non-parametric multiple imputation methods based on Classification and Regression Tress (CART) or Random Forests (RF) algorithms. These two methods fall into the umbrella concept of "recursive partitioning", that allows for the modeling of internal interactions in the data by sequentially partitioning the data set into homogeneous subsets. Implementations of both methods for the language $R$ can be found in the packages mice (van Buuren and Groothuis-Oudshoorn, 2011) and CALIBERrfimpute (Shah, 2014).

### 4.5.1 Classification and Regression Trees

CART methods uses a decision tree as a predictive model that represent the observations $Y_{j^{-}}$as branches from which conclusions about $Y_{j}$, the leaves, can obtained. The kind of tree is determined by the type of target variable, classification trees for discrete $Y_{j}$ and regression trees for continuous $Y_{j}$.

Algorithm 7 summarizes the imputation method. It can be seen that the idea is similar to PMM, where the predictive mean is calculated by a tree model instead of a regression model, and the donor pool is specified by all observations in the corresponding leave. Note that the fitting step of the algorithm doesn't specify the kind of

```
Algorithm 7 Classification and Regression Trees
    Draw a bootstrap sample \(\left\{\dot{Y}_{j}^{\text {obs }}, \dot{Y}_{j-}^{\text {obs }}\right\}\) of size \(n_{\text {obs }}\) from \(\left\{Y_{j}^{\text {obs }}, Y_{j-}^{\text {obs }}\right\}\).
    Fit \(\dot{Y}_{j}^{\text {obs }}\) by a tree model \(h\left(Y_{j^{-}}\right)\)restricted to \(Y_{j^{-}}^{\text {obs }}\).
    For each \(Y_{i j}^{\text {mis }}, i=1, \ldots, n_{\text {mis }}\), let \(Z_{i j}=\left\{Y_{i^{\prime} j}^{\text {obs }}: h\left(Y_{i^{\prime} j^{-}}^{\text {obs }}\right)=h\left(Y_{i j}^{\text {mis }}\right), i^{\prime}=1, \ldots, n_{\text {obs }}\right\}\).
    Draw one donor \(Y_{i^{\prime} j}^{\star}\) from \(Z_{i j}\).
    Impute \(Y_{i j}^{\star}=Y_{i^{\prime} j}^{\star}\).
    Repeat steps 1 to \(5 M\) times to generate multiple imputations.
```

tree model, allowing the use of any type.
Van Buuren (2012) claims that CART methods are robust against outliers, can deal with multicollinearity and swekwed distributions, and are able to fit interactions and nonlinear relationships. Nevertheless, in a simulation study by Doove, Van Buuren, and Dusseldorp (2014) it is shown that, even if the method is better in some cases than PMM or the Bayesian Linear Regression when estimating the coefficient of an interaction term, it fails to reach nominal coverage levels consistently. One the attributed explanations is the sequential nature of the tree models leading to inexact imputation models due to sub optimal and unstable trees.

### 4.5.2 Random Forest

Recursive partitioning algorithms, like CART, are commonly criticized for overreacting to minor changes in the data and tend to overfit the models. Random forests (RF) are an alternative that differ from CART by constructing a multitude (forest) of tree models. The objective is to average many decision trees, reducing the variance and recurrence of unstable trees (Doove, Van Buuren, and Dusseldorp, 2014).

The algorithm needed for RF imputation is a modification of algorithm 7. The first two steps are replaced by a construction of $k$ bootstrapped data sets, $k$ being the number of trees in the forest, and the fitting of $k$ tree models. Optionally, each tree can be fitted using the full bootstrapped data set or randomly selecting the input variables. To avoid reduced variability by imputing based on an averaged tree, possibly due to the higher stability of the individual trees, the imputed value is randomly selected from the union of the $k$ donor pools. For more details on the algorithm see Doove, Van Buuren, and Dusseldorp (2014, Appendix A)

## Chapter 5

## Robust imputation with GAMLSS and mice

De Jong (2012) proposed a new imputation technique based on a class of generalized additive models for location, scale, and shape (GAMLSS), which were introduced by Rigby and Stasinopoulos (2005). The use of GAMLSS allows the flexible modeling of the location (e.g., the mean), the scale (e.g., variance), and the shape (e.g., skewness and kurtosis) of the distribution of the incompletely observed variable, given the observed data.

The original work on the imputation technique was limited since the method was only able to deal with missings in one variable, the implementation was numerically unstable, and although it was published by de Jong (2012) and de Jong, van Buuren, and Spiess (2016) there wasn't any software library that allowed its use by the general public. A new R library, named ImputeRobust, was created as part of this thesis, extending the mice package with a class of GAMLSS imputation functions.

This chapter describes the GAMLSS-based imputation method and the referred software library. Section 5.1 introduces the required model at the basis of the developed method. Section 5.2 shows how imputed values are obtained and explains the algorithm. Section 5.3 provides details of the software and examines how it can be adjusted. Section 5.4 presents an example of real usage of the ImputeRobust library. Section 5.5 discusses theoretical considerations and limitations of the imputation method.

### 5.1 GAMLSS

The assumptions made by the Bayesian linear regression method described in section 4.1 are quite strong, even if extended with the help of generalized linear models. Its
most flexible formulation uses a linear prediction function to model the conditional expectation and variance of the variable with missing values $Y_{j}$.

The imputation technique developed by de Jong (2012) and de Jong, van Buuren, and Spiess (2016) also proposes to impute missing values based on a model, not unlike Bayesian linear regression. The main difference is that instead of assuming a Normal model in the Bayesian Linear Regression proposed by Rubin (1987), the newer approach designed by de Jong, van Buuren, and Spiess (2016) uses a model belonging to the class of GAMLSS (Rigby and Stasinopoulos, 2005).

Let $Y_{j}$ be the variable to be imputed, we assume that

$$
\begin{equation*}
Y_{j} \sim \mathscr{D}\left(g_{1}\left(\theta_{j}^{1}\right)=\eta_{1}, g_{2}\left(\theta_{j}^{2}\right)=\eta_{2}, \ldots, g_{K}\left(\theta_{j}^{K}\right)=\eta_{K}\right), \quad j=1, \ldots, n, \tag{5.1}
\end{equation*}
$$

where $\mathscr{D}$ is a parametric distribution with $K$ parameters $\theta_{j}^{k}, k=1, \ldots, K$ which are connected to the additive predictors $\eta_{k}$ by the known monotonic link functions $g_{k}(\cdot)$.

The parameters $\left(\theta_{j}^{1}, \theta_{j}^{2}, \theta_{j}^{3}, \theta_{j}^{4}\right)$ are typically associated with the location, scale, and shape parameters of the distribution $\mathscr{D}$. The actual value of $K$ determining the number of parameters depends on the distribution contemplated, being $K=4$ the maximum value considered. It should be clear from the notation that the distribution parameters are individually associated with each observation of $Y_{j}$. Finally, the additive predictors $\eta_{k}$ take the form:

$$
\begin{equation*}
\eta_{k}=\Omega_{k} \beta_{k}+\sum_{l=1}^{L_{k}} \mathbf{h}_{l k} \tag{5.2}
\end{equation*}
$$

where $\Omega_{k}$ is a fixed known design matrix, $\beta_{k}^{T}$ a vector of linear predictors, and $\mathbf{h}_{l k}=$ $h_{l k}\left(x_{l k}\right)$ is the vector evaluation of a unknown smoothing function $h_{l k}$ of the explanatory variables $x_{l k}$. Equation (5.2) is known as the semi-parametric additive formulation of GAMLSS and for specific combinations of $l$ and $k$ parametric, nonparametric and random-effects terms could be modeled (Rigby and Stasinopoulos, 2005; Stasinopoulos and Rigby, 2007).

The model presented relaxes the Bayesian linear regression model as described in Section 4.1, the latter being just a particular case. If $\mathscr{D}$ is taken as the normal distribution and the equation (5.2) is reduced to only a linear predictor, with appropriate link functions, the model is reduced to the Bayesian linear regression model.

### 5.2 Imputation

The chosen distribution, $\mathscr{D}$, in model (5.1) defines the type and number of parameters to be modeled. The default distribution was assumed to be normal by de Jong,
van Buuren, and Spiess (2016) and de Jong (2012), but other alternatives may be preferable. In principle, any family implemented in the gamlss package (Rigby and Stasinopoulos, 2005) can be selected. This close relationship with the gamlss package is an advantage since a user of the imputation method could adopt any extension of gamlss to restrict imputations to a certain range, e.g., by specifying a truncated or censored version of any distribution.

For the default normal distribution, the mean and variance are estimated, but other distributions may also require the estimation of the skewness and kurtosis. Adopting models with more parameters increases their flexibility and thus may increase the chance that the imputation procedure is proper in the sense of Rubin (1987). On the other hand, larger sample sizes may be needed to identify the larger number of parameters.

A caveat of the gamlss package is that it does not support Bayesian inference. Hence it is not possible to obtain multiple imputations by drawing from the posterior predictive distribution. De Jong, van Buuren, and Spiess (2016) and de Jong (2012) overcame this issue approximating the predictive posterior distribution by the bootstrap predictive distribution (Efron, 2012; Harris, 1989):

$$
\begin{equation*}
f^{\star}\left(Y_{j}^{m i s} \mid Y_{j}^{o b s}, Y_{-j}\right)=\int f\left(Y_{j}^{m i s} \mid \tilde{\eta}, Y_{-j}^{m i s}\right) f\left(\tilde{\eta} \mid \hat{\eta}\left(Y_{j}^{o b s}, Y_{-j}^{o b s}\right)\right) d \tilde{\eta}, \tag{5.3}
\end{equation*}
$$

where $\tilde{\eta}$ denotes the possible values of the imputation model parameters, $\hat{\eta}\left(Y_{j}^{o b s}, Y_{-j}^{o b s}\right)$ is an estimator of such parameters, and $f\left(\tilde{\eta} \mid \hat{\eta}\left(Y_{j}^{o b s}, Y_{-j}^{o b s}\right)\right)$ is the sampling distribution of the imputation parameters evaluated at the estimated values. The sampling distribution is simulated with a parametric bootstrap acting as a replacement for the posterior distribution of the imputation parameters. Algorithm 8 shows how the imputation process is realized after the distributional assumptions are made.

On the other hand, Umlauf, Klein, and Zeileis (2017) developed a conceptional framework called Bayesian additive models for location, scale, and shape (BAMLSS) because of the close similarities to GAMLSS. The key difference centers around a critical component of the fitting algorithm of GAMLSS: the maximization of a penalized likelihood function of the parametric vectors $\beta_{k}$ and hyperparameters of the smoothing terms $h_{l k}$ in equation (5.2). The newly proposed method provides Bayesian analysis features to GAMLSS by assuming the existence of sensible prior distributions for said parameters, instead of them being fixed.

The use of BAMLSS opens an alternative way to generate imputations. The method is very close to GAMLSS but with the selection of particular priors more general model terms could be defined. Umlauf, Klein, and Zeileis (2017) also created a modular

```
Algorithm 8 GAMLSS imputation
    : Fit model (5.1) using the observed data \(\left\{Y_{j}^{o b s}, Y_{-j}^{o b s}\right\}\) obtaining estimates \(\hat{\eta}_{1}^{j}, \hat{\eta}_{2}^{j}\),
    \(\hat{\eta}_{3}^{j}\) and \(\hat{\eta}_{4}^{j}\).
    Resample \(Y_{j}^{o b s}\) as follows:
```

$Y_{j_{\star}}^{o b s} \sim \mathscr{D}\left(\hat{\eta}_{1}^{j}, \hat{\eta}_{2}^{j}, \hat{\eta}_{3}^{j}, \hat{\eta}_{4}^{j}\right)$.
Define a bootstrap sample $B=\left\{Y_{j \star}^{\text {obs }}, Y_{-j}^{\text {obs }}\right\}$
Refit model (5.1) using $B$. This leads to adapted estimates $\tilde{\eta}_{1}^{j}, \tilde{\eta}_{2}^{j}, \tilde{\eta}_{3}^{j}$ and $\tilde{\eta}_{4}^{j}$.
Impute $Y_{j}^{\text {mis }}$ as follows:
$\tilde{Y}_{j}^{m i s} \sim \mathscr{D}\left(\tilde{\eta}_{1}^{j}, \tilde{\eta}_{2}^{j}, \tilde{\eta}_{3}^{j}, \tilde{\eta}_{4}^{j}\right)$.
: Repeat steps 2 to 5 M times to generate multiple imputations.
computational architecture that is available in the R package bamlss. The driving concept of the imputation with BAMLSS is the possibility of drawing posterior parameters with MCMC sampling. Algorithm 9 describes how imputations with BAMLSS can be obtained.

## Algorithm 9 BAMLSS imputation

Fit model (5.1) using the observed data $\left\{Y_{j}^{o b s}, Y_{-j}^{o b s}\right\}$ obtaining estimates $\hat{\eta}_{1}^{j}, \hat{\eta}_{2}^{j}$, $\hat{\eta}_{3}^{j}$, and $\hat{\eta}_{4}^{j}$.
: Draw estimates $\tilde{\eta}_{1}^{j}, \tilde{\eta}_{2}^{j}, \tilde{\eta}_{3}^{j}$ and $\tilde{\eta}_{4}^{j}$ using MCMC sampling with estimates $\hat{\eta}_{1}^{j}, \hat{\eta}_{2}^{j}$, $\hat{\eta}_{3}^{j}$, and $\hat{\eta}_{4}^{j}$ as starting points.
Impute $Y_{j}^{\text {mis }}$ as follows:

$$
\tilde{Y}_{j}^{m i s} \sim \mathscr{D}\left(\tilde{\eta}_{1}^{j}, \tilde{\eta}_{2}^{j}, \tilde{\eta}_{3}^{j}, \tilde{\eta}_{4}^{j}\right) .
$$

Repeat steps 2 to $5 M$ times to generate multiple imputations.

How the two methods compare to each other is something that will be discussed in the next chapter after the simulation results are presented. A relevant argument is given by Fushiki (2005) who showed that the bootstrap predictive distribution works better than the Bayesian predictive if the underlying model in the sampling distribution is misspecified.

De Jong (2012) and de Jong, van Buuren, and Spiess (2016) presented simulations results assuming a normal distribution when imputing a single incompletely observed variable in a bivariate data set. The results were valid even if the variable to be imputed was non-normal or counted, except for heavy-tailed distributions where the results were unsatisfactory and instances where the algorithm failed to imputed values. Salfran and Spiess (2015) expanded the scope of the initial research and showed that the good properties hold for more complex missing data structures and multivariate
data sets, although with the same problems.
To address the shortcomings of the previous research, Salfran and Spiess (2018b) published an R package called ImputeRobust. The software library is integrated with the popular imputation package mice (van Buuren and Groothuis-Oudshoorn, 2011) increasing its functionality with the inclusion of both GAMLSS and BAMLSS imputation algorithms. The package stabilizes gamlss enough to allow for more flexible distributions other than the normal with the expectation of improved results. Specifically, the four-parameter Johnson's SU distribution was extensively used, allowing for better results when imputing very asymmetric or leptokurtic data. Also, the package expands the distribution families provided by bamlss for fitting and MCMC sampling algorithms. The following section describes its implementation.

### 5.3 Software Implementation

Two imputing functions, mice.impute.gamlss() and mice.impute.bamlss(), with the addition of the fitting function ImpGamlssFit () represent the most important software procedures in the ImputeRobust library (Salfran and Spiess, 2018a,b).

The function ImpGamlssFit () is internal, and its job is to read in the data and model parameters to create a bootstrap predictive sampling function, i.e., it will work through steps 1 to 4 of Algorithm 8. The fitting step makes use of the gamlss package to fit model (5.1) based on (penalized) maximum likelihood estimation and adopting the default link functions. Rigby and Stasinopoulos (2005) and Stasinopoulos and Rigby (2007) provide a detailed description of the fitting algorithms and their $R$ implementation.

For the smoothing functions $h_{j k}$ in the additive predictors given by equation (5.2), the choice is between cubic splines, penalized splines or local polynomial regression surfaces. By default, and based on computational stability, we selected P-splines (penalized B-splines) to construct the smoothing terms. Specifically, the splines consist of 20 knots, a piece-wise polynomial of second degree, a second order penalty with smoothing parameters automatically selected using a local Maximum Likelihood criterion. A theoretical explanation of the selected P-splines can be found in Eilers, Marx, and Durbán (2015).

Even if the P-splines smoothing functions are considered to be stable in the gamlss package, sometimes the fitting algorithm may diverge. For example, if samples are too small and the volume of the predictor space gets too large, computational problems like exploding variances could arise. To prevent abnormal termination of the algorithm, the complexity of the model is automatically restricted, for instance, the degree of the polynomial, the order of the penalty, or the stopping time of the fitting
algorithm can be reduced.
The user can modify or increase further the degree of model simplification through optional arguments that can be introduced in the top mice() function call. These arguments, like cc or cyc, control the convergence criterion or number of cycles of the inner GAMLSS fitting function, respectively. A more exhaustive description can be found looking at the auxiliary functions glim.control() and gamlss.control() provided by the gamlss package (Rigby and Stasinopoulos, 2005).

Alternatively, since the estimation of the distribution parameters is done on an individual basis, the computational problems could be reduced to a subset of imputations with extreme values. Then, instead of decreasing the complexity of the full model, the simplification could be restricted to the extreme cases. In a worst-case scenario, a different imputation method can be used for such data points. The Boolean argument EV can be used to allow for extreme values correction.

The necessary $R$ formula objects for the model are automatically created by the function during execution time. The default and simplified imputation models can be controlled with the arguments gam.mod and mod.planb. These take the form of a list with elements specifying the type of smoother and its parameters. Another way of adjusting the definition of the models is the lin.terms argument. This last argument can be used to define which variables should enter model (5.2) linearly.

To improve the stability of the software, distributional parameters can be modeled as a constant term for all units, i.e. $\eta_{k}=C_{k}$ for some values of $k$ where $C_{k}$ is a constant, this is equivalent to say that $g_{k}\left(\theta_{j}^{k}\right)=C_{k}$ for $j=1, \ldots, n$. The selected family determines the value of $K$ in equation (5.1) and therefore how many parameters are to be modeled. The argument n . ind. par sets the maximum number of parameters to be fitted with the semi-parametric additive model (5.2). For example, if the Johnson's SU family (a four parameter continuous distribution) is selected and n . ind. par $=2$, then the mean and the deviation are vectors, but the shape parameters are restricted to be the same for all units. The numbers of individually fitted parameters in the simplified model takes the same value as n .ind.par but can be set to a different value through argument n.par.planb.

The function mice.impute.gamlss() has the same structure as the imputation methods included in the mice package, meaning that method = "gamlss" is a valid argument that can be directly passed to the mice() function. As it was established in the previous section, the normal distribution is the default response distribution family used by the fitting and imputation methods, but a different distribution family can be utilized instead by changing the value of the argument family.

For convenience, additional functions are included in the package that are equal to mice.impute.gamlss() but with family and n.ind. par arguments preset to non-
default values. This allows users to mix different gamlss imputation methods within one call to the function mice(). All functions are variants of mice.impute.gamlss() where the "gamlss" part is replaced by a method from Table 5.1. The name of the function is a reference to the corresponding family from gamlss.family (see Stasinopoulos and Rigby, 2007)

| Method | Model distribution |
| :--- | :--- |
| gamlssNO | Normal |
| gamlssBI | Binomial |
| gamlssGA | Gamma |
| gamlssJSU | Johnson's SU |
| gamlssPO | Poisson |
| gamlssTF | Student's t |
| gamlssZIBI | Zero inflated Binomial |
| gamlssZIP | Zero inflated Poisson |

Table 5.1: Included univariate gamlss imputation models.
The function mice.impute.bamlss() is very similar to its gamlss counterpart. Arguments like gam.mod, lin.terms, n.ind.par, and family are still valid for this function as a step of the algorithm is the fitting of a GAMLSS model. The argument that controls the behavior of the MCMC sampler is the fundamental difference. This is done with propose that sets the propose function for model terms. The default proposal function is set to "iwlsC" which implies that the smoothing variances of univariate terms are sampled assuming an inverse gamma prior. A detailed description of the methods provided by bamlss can be found in Umlauf, Klein, and Zeileis (2017).

### 5.4 Usage

In what follows, we show with an example how ImputeRobust can be utilized in an estimation task together with mice. Let us assume that we have a hypothetical data set with 1000 incompletely observed units and five variables. We desire to estimate the parameters in the linear regression of one dependent on four independent variables.

The four independent variables $\left(X_{1}, \ldots, X_{4}\right)$ are weakly correlated and are random samples from four specific distributions: the standard normal, the Chi-squared, the Poisson and the Bernoulli distribution, respectively. The dependent variable, $Y$, is created according to the linear regression model:

$$
\begin{equation*}
Y=\beta_{0}+X_{1} \beta_{1}+X_{2} \beta_{2}+X_{3} \beta_{3}+X_{4} \beta_{4}+\epsilon, \quad \epsilon \sim N\left(0, \sigma^{2}\right) . \tag{5.4}
\end{equation*}
$$

The vector of linear predictors, $\beta$, and the error variance, $\sigma^{2}$, are chosen so that the coefficient of determination, $R^{2}$, is 0.5 .

A non-monotone MAR mechanism dependent on $Y$ and $X_{1}$ was used to delete values in $X_{2}, X_{3}$ and $X_{4}$. These three variables are missing between $24 \%$ and $48 \%$ of their values. Appendix A contains the R code needed to replicate the incomplete data set.

The imputation task can be performed with a simple call of the mice() function:

```
> require(ImputeRobust)
> imps <- mice(data, method = c("", "", "gamlssGA", "gamlssPO",
    "gamlssBI"), seed = 8913)
iter imp variable
    1 1 X.4 X. }3\mathrm{ X. 2
    1 2 X.4 X. }3\mathrm{ X.2
    1 3 X.4 X. }3\mathrm{ X.2
    1 4 X.4 X. }3\mathrm{ X.2
    1 5 X.4 X. }3\mathrm{ X.2
    2 1 X.4 X. }3\mathrm{ X. 2
    2 2 X.2 X. }3\mathrm{ X.4
```

All output is generated by the mice package, for details see van Buuren and GroothuisOudshoorn, 2011. The result is an object of class Multiply Imputed Data Set (mids) with contents:

```
> print(imps)
Multiply imputed data set
Call:
mice(data = data, method = c("", "", "gamlssGA", "gamlssPO",
    "gamlssBI"), seed = 8913)
Number of multiple imputations: 5
Missing cells per column:
    y X. }1\mathrm{ X. 2 X. }3\mathrm{ X. }
    O 0 477 461 242
```

Imputation methods:

| y | X.1 | X. 2 | X. 3 | X. 4 |
| ---: | ---: | ---: | ---: | ---: |
| $" " ~$ | $" "$ | "gamlssGA" | "gamlssPO" | "gamlssBI" |

VisitSequence:

X. }
X.4 1 1 1 1 1 0
Random generator seed value: 8913
```

The value of argument method in the mice function call implies that the distribution assumed is the Gamma for $X_{2}$, the Poisson for $X_{3}$, and the Binomial for $X_{4}$. This allows for the imputation of realistic values as compared to the default normal distribution. Nevertheless, the objective of MI is to achieve the statistical validity of the estimated values (Rubin, 1996). Sometimes it may be better to use a more flexible model even if the imputed values are "unrealistic", for example using a distribution with larger support, or one being continuous when the variable to be imputed is discrete (see de Jong, 2012; de Jong, van Buuren, and Spiess, 2016; Salfran and Spiess, 2015). Figure 5.1 shows the distribution of the original and imputed data with onedimensional scatter plots, also known as strip plots.

The model of interest, as per equation (5.4), is the linear regression of $Y$ on $X_{1}$, $X_{2}, X_{3}$, and $X_{4}$ that created the original data set. The true value of the regression coefficient is $\mathrm{c}(1.8,1.3,1,-1)$. The imputed data sets can be analyzed as follows:

```
> fit <- with(imps, lm(y ~ X.1 + X.2 + X.3 + X.4))
> round(summary(pool(fit)), 2)
```

|  | est | se | t | df | $\operatorname{Pr}(>\|\mathrm{t}\|)$ | lo 95 | hi 95 | nmis | fmi lambda |  |

| X.3 | 0.97 | 0.14 | 6.99 | 9.64 | 0.00 | 0.66 | 1.28 | 461 | 0.69 | 0.64 |
| X.4 | -0.92 | 0.41 | -2.24 | 12.99 | 0.04 | -1.81 | -0.03 | 242 | 0.60 | 0.55 |

### 5.5 Discussion

The imputation method based on GAMLSS requires the selection of the conditional distribution $\mathscr{D}$ for each of the variables to be imputed. The decision of which distribution family to use is a problem that could potentially result in deficient imputed values.

to be treated with the algorithm. In this regard, the most obvious symptoms of issues are manifested as outliers in a set of imputed values, which may lead to a biased estimation. With the higher flexibility allowed, some responsibility is put on the imputer to explore the results obtained.

## Chapter 6

## Simulation Experiment

In this chapter, the simulation experiments designed to explore the performance of the imputation methods described in Chapters 4 and 5 are described.

The multiple imputation techniques described in Chapter 4 take advantage of Rubin's (1987) work, and they all share the property that no proof exists showing that inferences based on the multiply imputed data sets are valid in all situations of potential interest. The properties of scientifically interesting estimators based on multiply imputed data sets can therefore systematically be studied only in simulation experiments.

De Jong (2012) compared the version of his GAMLSS imputation algorithm to the Bayesian Linear regression algorithm (Section 4.1), PMM (Section 4.3.1) and aregImpute (Section 4.3.2). His results show that these three methods were sensible to model misspecification. In any case, recent approaches to missing value compensation still develop and propose to use these methods or derivatives of them, PMM in particular (e.g., Gaffert, Meinfelder, and Bosch, 2016; Morris, White, and Royston, 2014; Tutz and Ramzan, 2014). Salfran and Spiess (2015) presented simulation results testing the mentioned methods with different experimental conditions. They also included most of the imputation methods described in Chapter 4 and GAMLSS.

### 6.1 Experimental Design

The goal of the simulation study is to explore if the inference based on multiply imputed data sets is valid under various experimental conditions. All simulation cases focus on the estimation of the coefficients in a linear regression model when the predictor variables are incompletely observed. This a particular case of the scientific problem of interest discussed in Chapter 2. We decided to concentrate on this model for the simulations because we intended to partly replicate the results of de Jong (2012) and
de Jong, van Buuren, and Spiess (2016). Though, we extended the scope of the original design to encompass more realistic research situations and test the imputation algorithm with more general data sets.

All simulations were run with R (R Core Team, 2017). Algorithm 10 provides an outline of how the simulations are done. The various experimental conditions are controlled according to steps 1 and 2 of the algorithm. These distinct settings can be divided into several groups which will be discussed in the next sections.

```
Algorithm 10 Simulation experiment
    Generate the data set.
    Delete values according to a missing data mechanism.
    Multiply impute the incomplete data set using different imputation techniques.
    Calculate point and variance estimates for the coefficients of a linear regression
    using the initially complete data set, the completely observed part and the multiply
    imputed data set.
    Repeat steps \(1-4 \mathrm{~N}\) times.
```

The imputation methods used in step 3 , are the same as described in chapters 4 and 5 . Table 6.1 summarizes the methods employed and the corresponding R library that provides them. Like Salfran and Spiess (2015) also did, we include diverse copies of the PMM method with different values of donors (1, 3, 5, 10 and 20). The square root of the sample size is also considered as the number of donors (see Dahl, 2007). To check the current state of the GAMLSS imputation software modifications, we also evaluated several copies of the algorithm with different distribution families or fitting parameters. All other methods use their default settings.

After the simulations are done we calculate the means of the estimates, the positive square root of the mean of variance estimates, the sample variance of the estimates over the simulations, and the proportion of cases for which the confidence intervals

Table 6.1: List of tested imputation methods

| Method | library (version) |
| :--- | :--- |
| Bayesian Linear Regression | mice (2.46.0) |
| Amelia | Amelia (1.7.4) |
| Predictive Mean Matching | mice $(2.46 .0)$ |
| aregImpute | Hmisc (4.0-3) |
| MIDAStouch | mice (2.46.0) |
| IRMI | VIM $(4.7 .0)$ |
| CART | mice (2.46.0) |
| Random Forest | mice (2.46.0) |
| GAMLSS imputation | ImputeRobust (1.2) |

cover the true value. The assessment of the quality of the imputation methods is based on four criteria:

- Bias, being the difference between the mean of the estimators of the regression coefficient and the known true value. It should be as close as possible to 0 .
- Coverage, based on the proportion of $95 \%$ confidence intervals covering the true value. Every simulation could be thought of as an independent random draw of a binary variable taking on the value one if the confidence interval covers the true value and zero otherwise. When all assumptions are met, $95 \%$ confidence intervals cover the true parameter value with probability 0.95 . This means, for example, that if 1000 simulations are performed, the coverage rate over the simulations should be in the confidence interval [0.936, 0.964]. The ideal result is if mean estimates are approximately unbiased with coverage within the above limits. Under-Coverage (values below the interval) indicates an invalid inference. Over-Coverage with an unbiased estimator illustrate what's called confidence validity (Rubin, 1996).
- Efficiency, as a measure of the standard deviation of the estimators over the simulations. It is calculated by taking the positive square root of the mean of the estimated variances in the simulations. While the bias and coverage determine the validity of the imputation method, we are interested in the overall performance of the imputation methods. This is an auxiliary benchmark. If two imputation methods are equally valid, the one with smaller variance should be preferred.
- Relative efficiency, given as the ratio of the mean variance estimates and the sample variance across simulations. This criterion contrasts the values of Rubin's variance estimator with the estimated variance over the simulations. The ideal result is a ratio close to 1 . Values below or above 1 are symptoms of underestimation or overestimation of the variance. Likewise the efficiency this is a secondary criterion.

### 6.1.1 Single predictor

The first experimental condition partly includes and replicates the "simple design" used by de Jong (2012) and de Jong, van Buuren, and Spiess (2016). The data generating process (DGP) is based on the linear regression given by

$$
\begin{equation*}
y=\beta_{0}+\beta_{1} x+\epsilon, \quad \epsilon \sim N\left(0, \sigma^{2}\right), \tag{6.1}
\end{equation*}
$$

where $\beta_{0}=0$ and $\beta_{1}=1$. Three parameters are modified to generate diverse simulations situations. These are the distribution of $x$, the coefficient of determination $R^{2}$, and the sample size $n$.

The distribution of the predictor variable $x$ can be any option between a standard normal, a skew-normal with shape parameter $\lambda=5$, uniform between 0 and 1 , a squared uniform (beta), student's t with $v=3$ degrees of freedom, a Poisson with rate parameter $\lambda=3$, or a chi-squared with $k=3$ degrees of freedom. The value of $R^{2}$ is $0.25,0.5$, or 0.75 and is adjusted with the variance $\sigma^{2}$ of the error in the linear model once a distribution is selected. The sample size, $n$, varies between 50, 200, and 1000 units.

Every possible combination of distribution, coefficient of determination and sample size is analyzed. Each study is simulated $N=1000$ times and $m=10$ imputations are realized for each replication. All distributions but the chi-squared were considered by de Jong (2012). The present design changes besides the rate parameter of the Poisson distributed variable and the sample sizes. Considering 50 units instead of 500 makes more sense in psychological applications where the sample size is often small. Also, it is a harder test for the stability of the GAMLSS imputation method.

For all cases, roughly $40 \%$ of $x$ is deleted according to the missing data mechanism (MDM):

$$
\mathrm{P}(R=0 \mid y)= \begin{cases}0.3 & \text { if } y \leq \tilde{y}  \tag{6.2}\\ 0.9 & \text { a.o.c. }\end{cases}
$$

where $\tilde{y}$ is the sample median. This means that $x$ is MAR with respect to $y$, with probability of being missed equal to 0.3 if $y$ is below the median and 0.9 otherwise. The strength of the MAR mechanism is dependent on $R^{2}$ with higher values leading to more selective thinning out of the sample space. This MDM is exactly the one that de Jong (2012) and de Jong, van Buuren, and Spiess (2016) utilized.

### 6.1.2 Multivariate set

We extended the scope of the first experiment by moving into the analysis of multivariate data set with multiple incompletely observed variables. The main reason for this is to test the robustness of the latest version of ImputeRobust in a more realistic scenario. Besides the multivariate data sets, we also test for the effects of different missing mechanisms and patterns of missingness. For this, we define two MDM with a differing selectivity of the region from which values are deleted that we call "strong" and "weak MDM." Further, the missing pattern can be either monotone or not. The combination of MDM and missing pattern applied to every multivariate data set define
the four remaining experimental conditions tested.
The DGP chosen to simulate the multivariate data set is similar to the one already used in the example of Section 5.4. It is based on the linear regression of four correlated covariates $\left(x_{1}, \ldots, X_{4}\right)$ and normally distributed homoscedastic errors. In each simulation, the distributions of $x_{1}, X_{3}$ and $X_{4}$ are fixed to be the standard normal, the Poisson with rate parameter $\lambda=3$, and the Bernoulli with mean parameter $\pi=0.4$, respectively. The distribution of $X_{2}$ is continuous and may vary between a standard normal, a chi-squared or a student's $t$, these last two with 3 degrees of freedom each.

The four covariates are weakly correlated according to the correlation matrix:

$$
\left(\begin{array}{cccc}
1 & 0.15 & 0.1 & -0.1  \tag{6.3}\\
0.15 & 1 & 0.25 & 0.05 \\
0.1 & 0.25 & 1 & 0 \\
-0.1 & 0.05 & 0 & 1
\end{array}\right)
$$

To create the correlated structure, a sample from a four-dimensional multivariate normal distribution with mean zero and correlation matrix given by (6.3) is drawn. This is transformed to the desired sample by calculating the values of the standard normal cumulative distribution function (CDF) for each simulated value and then using the inverse CDF corresponding to each target distribution.

A dependent variable $y$ is generated according to the linear regression model,

$$
\begin{equation*}
y_{i}=\beta_{0}+x_{i 1} \beta_{1}+x_{i 2} \beta_{2}+x_{i 3} \beta_{3}+x_{i 4} \beta_{4}+\epsilon_{i}, \quad \epsilon_{i} \sim N\left(0, \sigma^{2}\right) . \tag{6.4}
\end{equation*}
$$

As with the simple experiment the sample size is either 50, 200 or 1000 units. The true values of the parameters weighting the predictors change depending on the distribution of $X_{2}$, but are fixed at the beginning of each simulation experiment. If $X_{2}$ follows a standard normal distribution the vector of parameters is $\beta=(0,1.3,1.5,0.8,2.5)$. If $X_{2}$ follows instead a $t$ distribution then $\beta=(0,1,1,0.95,1.5)$. Finally, if $X_{2}$ comes from a chi-squared distribution then $\beta=(0,2,1.1,1.5,4)$. The difference in regression coefficients is due to the desire of keeping the effect of each predictor at the same level, as measured by the partial eta-squares. The error variance $\sigma^{2}$ is chosen so that the coefficient of determination, $R^{2}$, equals 0.5 . The code in Appendix A can be adapted to get the desired DGP.

We define two MAR mechanism that deletes values on $X_{2}, X_{3}$ and $X_{4}$ dependent on $y$ and $x_{1}$. The two mechanisms are called "strong" and "weak MDM." Under both conditions, the probabilities of not observing a value are the same, being 0.45 for $X_{2}, 0.31$ for $X_{3}$, and 0.079 for $X_{4}$, leading to a similar proportion of missing values. The difference consists in the reduction of the selectivity, that is, the "strong MDM"
deletes values in one specific region of the space more aggressively as compared to the "weak MDM." Figures 6.1 and 6.2 show this difference. In the first one, it can be seen that values on the right half side of the distribution of the variables are systematically deleted. On the other hand, in the second case values are more evenly deleted on both sides.

Let $R_{i j}$ be the response indicator of $x_{i j}$, where $R_{i j}=1$ if $x_{i j}$ is observed and $R_{i j}=0$ if $x_{i j}$ is missing. In the first part of the remaining simulation experiments, we establish monotone missing patterns to avoid possible incompatibility issues, e.g., the non-existence of a regular distribution of the variables with missing values or numerical issues concerning convergence of the MICE algorithm. This is achieved by conditioning the MDM of a variable to the response indicator $R$ of the previous one. First, calculate the value $r_{i}^{\star}=2 y_{i}+x_{i 1}$, then under the "strong MDM" conditions, values of $X_{2}, X_{3}$ and $X_{4}$ are deleted according to the following rules:

$$
\begin{gather*}
\mathrm{P}\left(R_{i 2}=0 \mid r_{i}^{\star}\right)=\left\{\begin{array}{ll}
0.1 & \text { if } r_{i}^{\star} \leq r_{0.5}^{\star} \\
0.8 & \text { elsewhere }
\end{array},\right.  \tag{6.5}\\
\mathrm{P}\left(R_{i 3}=0 \mid r_{i}^{\star}, R_{i 2}=0\right)=\left\{\begin{array}{ll}
0.68 & \text { if } r_{i}^{\star} \leq r_{0.3}^{\star} \\
0.71 & \text { elsewhere }
\end{array} \quad \operatorname{Pr}\left(R_{i 3}=0 \mid r_{i}^{\star}, R_{i 2}=1\right)=0\right.  \tag{6.6}\\
\mathrm{P}\left(R_{i 4}=0 \mid r_{i}^{\star}, R_{i 2}=0, R_{i 3}=0\right)=0.25, \quad \operatorname{Pr}\left(R_{i 4}=0 \mid r_{i}^{\star}, R_{i 3}=1\right)=0 \tag{6.7}
\end{gather*}
$$

where $r_{p}^{\star}$ is the $p$-quantile of the $r^{\star}$ values. In equations (6.7) points out that $R_{4}$ is MCAR given $r^{\star}, R_{2}$ and $R_{3}$. For the "weak MDM" equations (6.5) and (6.6) turn into:

$$
\begin{gather*}
\mathrm{P}\left(R_{i 2}=0 \mid r_{i}^{\star}\right)= \begin{cases}0.35 & \text { if } r_{i}^{\star} \leq r_{0.5}^{\star}, \\
0.55 & \text { elsewhere }\end{cases}  \tag{6.8}\\
\mathrm{P}\left(R_{i 3}=0 \mid r_{i}^{\star}, R_{i 2}=0\right)=\left\{\begin{array}{ll}
0.695 & \text { if } r^{\star} \leq r_{0.4}^{\star} \\
0.703 & \text { elsewhere }
\end{array}, \quad \operatorname{Pr}\left(R_{i 3}=0 \mid r_{i}^{\star}, R_{i 2}=1\right)=0\right. \tag{6.9}
\end{gather*}
$$

and the missings values for $X_{4}$ are still generated according to equation (6.7). Since the parameters in the DGP and MDM do not depend on each other, and the mecha-

Figure 6.1: Scatter plot of the missing and observed values using example data from section 5.4. From left to right and from top to bottom: chi-squared $\left(X_{2}\right)$, Poisson $\left(X_{3}\right)$, Binomial $\left(X_{4}\right)$ and dependent ( $y$ ) variables. The independent variables are plotted against the linear response tendency function $r^{\star}$. The dependent variable against the linear predictor $\beta \times X$. Values are missing according to the "strong" mechanism.
nisms are MAR, both missing mechanisms are ignorable.
An objective of the current work is to actually test the developed and existing imputation methods in a scenario as realistic as possible. Thus, in the final part of the simulation experiments we decided to drop the restriction on the monotonicity of the MDM. We use two non-monotone missing mechanisms derived from the "strong" and "weak MDM". In short, the dependency on whether the previous value is observed or not is dropped. The "strong MDM" becomes:

$$
\mathrm{P}\left(R_{i 2}=0 \mid r_{i}^{\star}\right)=\mathrm{P}\left(R_{i 3}=0 \mid r_{i}^{\star}\right)=\left\{\begin{array}{ll}
0.1 & \text { if } r_{i}^{\star} \leq r_{0.5}^{\star} \\
0.8 & \text { elsewhere }
\end{array}, \quad \operatorname{Pr}\left(R_{i 4}=0 \mid r_{i}^{\star}\right)=0.25\right.
$$

and the "weak MDM":

$$
\mathrm{P}\left(R_{i 2}=0 \mid r_{i}^{\star}\right)=\mathrm{P}\left(R_{i 3}=0 \mid r_{i}^{\star}\right)=\left\{\begin{array}{ll}
0.35 & \text { if } r_{i}^{\star} \leq r_{0.5}^{\star} \\
0.55 & \text { elsewhere }
\end{array}, \operatorname{Pr}\left(R_{i 4}=0 \mid r_{i}^{\star}\right)=0.25\right.
$$

Figure 6.2: Scatter plot of the missing and observed values using example data from section 5.4. From left to right and from top to bottom: chi-squared ( $X_{2}$ ), Poisson $\left(X_{3}\right)$, Binomial $\left(X_{4}\right)$ and dependent $(y)$ variables. The independent variables are plotted against the linear response tendency function $r^{\star}$. The dependent variable against the linear predictor $\beta \times X$. Values are missing according to the "weak" mechanism.

### 6.2 Single Predictor Results

In what follows the results of the simulation study described in section 6.1.1 are presented. The outcome of the experiments is summarized as shown in table 6.2.

Table 6.2: Example of results

|  | $n=50$ |  |  |  | $n=200$ |  |  |  | $n=1000$ |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | bias | cov | sd | ratio | bias | cov | sd | ratio | bias | cov | sd | ratio |
| $\mathrm{R}^{2}=0.25$ |  |  |  |  |  |  |  |  |  |  |  |  |
| COM | 0.002 | 0.956 | 0.254 | 1.023 | 0.004 | 0.958 | 0.123 | 1.026 | 0.001 | 0.945 | 0.055 | 0.986 |
| CCA | -0.147 | 0.934 | 0.320 | 0.972 | -0.122 | 0.878 | 0.153 | 1.005 | -0.126 | 0.543 | 0.068 | 0.933 |
| NORM | -0.068 | 0.960 | 0.346 | 1.056 | -0.008 | 0.961 | 0.156 | 1.038 | -0.004 | 0.944 | 0.069 | 0.985 |
| AMELIA | -0.017 | 0.941 | 0.343 | 0.996 | 0.006 | 0.956 | 0.155 | 1.036 | -0.002 | 0.941 | 0.068 | 0.983 |
| PMM-1 | -0.040 | 0.939 | 0.375 | 0.970 | -0.000 | 0.900 | 0.156 | 0.851 | -0.003 | 0.896 | 0.066 | 0.826 |
| ... |  | $\cdots$ | . | $\ldots$ | . | $\ldots$ | .. | . |  |  |  |  |

Note: If $n=50$, results for aI-kNN are based on 373 , those for aI-W on 372 successful simulations.
The first column shows the tested methods. The complete data set and complete case analysis are described as COM and CCA respectively. These are followed by NORM for

Bayesian Linear Regression (section 4.1) and AMELIA (section 4.2). Next, several variants of hot deck imputation methods (section 4.3) are included, in particular, copies with a different number of donors for the Predictive Mean Matching. These PMM variants are presented as PMM-N, where $N$ is either $1,3,5,10,20$ or $D$ (meaning the square root of the sample size). AregImpute and Midastouch are given by AREG and MIDAS respectively. The Iterative Robust Model-Based Imputation method (section 4.4) follows the list as IRMI. The recursive partitioning methods (Section 4.5 are included as CART for classification and regression trees and RF for random forests. Finally, the list is completed with differing alternatives of GAMLSS imputing methods: BAMLSS and GAMLSS (both assuming a Normal distribution for the response variable), and GAMLSSJSU testing the assumption of the four parameters Johnson's SU distribution for the response variable (see chapter 5.1 for details).

The following twelve columns are divided into three groups of four, for each of the tested sample sizes: 50, 200 and 1000. The four columns in each group report the four criteria defined in section 6.1. The first column, indicated as bias, shows the estimated mean bias of the imputation method. A gray gradient is used as the background for the cells, starting in white for an estimated bias of 0 and getting darker as it increases. The second column, indicated as cov, contains the coverage probability of the imputation methods. Values in the acceptable range are colored green, undercoverage is red and over-coverage, which is confidence valid is orange. The third column, indicated by sd, presents the efficiency of the estimators. Finally, the fourth column, denoted ratio, shows the values of relative efficiency between the mean variance of the estimators and estimated variance across simulations.

The results for the different values of coefficient of determination are included in the same table. In the first column a line with the text $\mathrm{R} 2=0.25,0.50$ or 0.75 is included to indicate said value.

### 6.2.1 Normal

The first simulation experiment adopts a normal distribution for the predictor variable. Figure 6.3 represents the effects of the MDM given by equation (6.2) on the distribution of the missing values where it is shown that the MDM selectively removes observed values on one side of the data set. This simple condition is meant to serve as a standard for all imputation methods. Table 6.3 presents the full results of this simulation study.

Since the MDM is MAR, CCA is expected to fail, and in fact, it does. Regardless of the value $R^{2}$ complete case analysis leads to invalid results due to under-coverage

Figure 6.3: Scatter plots of both the direct and reverse regression when the covariate is normally distributed. The red circles are observed values, and the blue triangles are missing. The coefficient of determination is 0.5 .
with values ranging between 0.434 and 0.554 for $n=1000$. With increasing sample size the under-coverage problem only gets worse.

A quick glance at the table shows that the smallest sample size produces the largest biases while at the same time it contains the largest proportion of methods with coverage in the valid or confidence valid range. This result can be explained by the large overestimation of the variances. This is known as the "self-correcting" property of Multiple Imputation (Rubin, 2003) which is a form of compensation for the missing information.

NORM results are almost perfect in all three cases. This is no surprise since $X$ and $y$ are bivariate normally distributed fulfilling all required assumptions of the Bayesian Linear Regression imputation method. The only virtual difference between this imputation method and the analysis with COM is the larger standard errors which in the case of $R^{2}=0.5$ and $n=50$ leads to over-coverage ( $\operatorname{cov}=0.966$ ). AMELIA also relies on normality assumptions and in this simple scenario should perform well. The results are almost as good as NORM, but when $R^{2}=0.5$ and $n=1000$ it does suffer from under-coverage.

There is a general pattern to the PMM methods. If we fix the number of donors and increase the sample size, i.e., we move in a horizontal line in the table, the bias of the imputation methods decreases, as do the mean estimated standard errors. The problem is the drop in coverage probabilities leaving almost no valid PMM method for $n=200$ and none for $n=1000$ (cov $\leq 0.909$ ). The standard errors are similar to NORM but the ratio between the mean variance and estimated variance across simulations is smaller. This indicates that the estimated variances decrease too fast in comparison to the true variance, and it may explain the under-coverage. Moving in the other direction, i.e., fixing the sample size and increasing the number of donors, there is not
a perfect monotone relationship concerning bias and coverage. For a larger number of donors, the bias increases but coverages start getting better up to a maximum and then decrease again. For example, when $R^{2}=0.25$ from 1 up to 10 donors the coverage increase, and then for 20 and $\sqrt{1000} \approx 31.6$ donors decrease again. Practically, only when $n=50$, most PMM methods can provide estimates with valid coverage, thanks to the "self-correcting" property and at the expense of large biases.

AREG and MIDAS perform similar to each other, being the former the best of the two for $R^{2}=0.25$ and $R^{2}=0.75$ and the latter the best if $R^{2}=0.5$. Both methods are almost unbiased for $n \geq 200$ but suffer from under-coverage and are thus invalid (cov $\leq 0.933$ ). The only valid cases are provided by MIDAS when $n=50$.

IRMI is the worst method overall with extreme results of bias and under-coverage, being this latter statistic close to 0 for $n=200$ and 0 for $n=1000$. The standard errors and the ratio constitute the largest values of these measures of all imputation methods. The results are evidence of a severe issue in the theory or implementation of this method. They may be caused by the wrong classification of "extreme" values which are just outliers due to the thinning of regions with the MDM.

CART and RF perform almost identical to each other in terms of all considered measures. Both methods suffer from under-coverage although the estimated bias is relatively non existent. RF leads to valid results only in two cases, for $n=50$ and $R^{2} \geq 0.5$.

Next in the list of imputation methods are the GAMLSS algorithms. The BAMLSS method suffers from under-coverage and fails to be valid (cov $\leq 0.927$ ). As the sample size increases the method becomes unbiased, and it shows the smallest standard error of all imputation methods. A ratio of variances being approximately 0.86 implies a systematic underestimation of the error. Both GAMLSS and GAMLSS-JSU are unbiased and provide valid estimation or confidence valid in the case of the Johnson's SU alternative when $R^{2}=0.75$ and $n \geq 200$. They have the largest standard errors, after IRMI, with GAMLSS-JSU producing the greater values of the two.

The difference between BAMLSS and GAMLSS is the use of the MCMC sampling to simulate the Bayesian posterior and the Bootstrap Predictive Sampling. Seeing the different results concerning the validity and the estimated errors and ratio statistics, a reason for the problem of BAMLSS may be a lack of variability in the MCMC sampling step of algorithm 9.

### 6.2.2 Skew-Normal and Chi-squared distribution

The second and third simulation experiments adopt a skew-normal with shape parameter $\lambda=5$ or a chi-squared distribution for the predictor variable. Figure 6.4 displays the effects of the MDM on the observed data. These two distributions are selected because of their skewness. In these cases, the reverse regression is not linear, and the errors are heteroscedastic. It is expected that methods like NORM, that rely on normality assumptions, will fail in this scenario.

Figure 6.4: Scatter plots of both the direct and reverse regression when the covariate is skew normally distributed with shape parameter $\lambda=5$ (top row) or chi-squared with 3 degrees of freedom (bottom row). The red circles are observed values, and the blue triangles are missing. The coefficient of determination is 0.5 .

The results in tables 6.4 and 6.5 show that when $n=50$ the "self-correcting" property again leads to confidence valid results even if estimation is biased. The methods show values of coverage higher than 0.872 for this sample size, except for BAMLSS whose coverage is around 0.71 .

Section 2.3.2 shows that CCA in the current experimental scenario is not valid, and the tables support the statement, although it is as bad as in the Normal case. In table 6.4 it can be seen that CCA has a small bias, with coverage values that are above
0.813. In table 6.5 CCA is even better. The bias is smaller, and the coverage is the best after COM, GAMLSS and GAMLSS-JSU, reaching validity even if $n=50$ or $n=1000$ with $R^{2}=0.75$. Both the skew normal and the chi-squared distributions used, are skewed to the right and, precisely, the MDM selectively deletes values on the right side of each distribution. The consequence of this process seems to be that the missing values, at least for these two distributions, don't make CCA as bad as when $X$ is normally distributed.

NORM fails to produce valid results in most cases, being even worse than CCA especially if $R^{2} \geq 0.5$. For example, if $X$ is skew normally distributed, $R^{2}=0.5$ and $n=1000$ the coverage of NORM is 0.535 while CCA has coverage of 0.833 . Given the values of standard errors and the ratio, the problem of NORM seems to be caused by the bias of the method when the MDM is more selective. In the case of $X$ being chi-square distributed coverage values of NORM can be as low as 0.107 . Since AMELIA relies on the same normality requirements of NORM, the simulation results are a close match. This behavior is maintained throughout the remaining simulation experiments.

The Hot Deck methods: PMM, AREG, and MIDAS have negligible biases as the sample size increases, but the results are generally invalid. Only two acceptable estimations are obtained when $n \geq 200$. The first is provided by PMM-20 if $R^{2}=0.75$ and $n=200$, for both simulation settings. The second is given by MIDAS if $R^{2}=0.5$ and $n=1000$. The coverage rates oscillate between 0.864 and 0.928 . Concerning the number of donors, the same pattern that was observed for PMM in the Normal case is noticed again here. The coverage decrease in the horizontal direction together with a quick reduction of the ratio of errors. In the vertical direction, the bias and the coverage vary in a parabolic fashion, bias (coverage) decreasing (increasing) up to a certain point and the moving in the opposite way.

IRMI shows again the same extreme behavior as in the previous experiment. This happened too in all experimental settings. The method will be excluded in any further discussion unless it is required by any special reason. The "robust" part emphasized in the name of this method seems to be its weakness.

CART and RF are practically unbiased, but in the current scenario, the coverage ranges from 0.854 to 0.935 , below the nominal interval. RF provides its only valid estimation if $R^{2}=0.75$ and $n=1000$ when $X$ is chi-square distributed while CART is never valid. The have similar values in all criteria, the only difference is the slightly smaller estimated standard error of CART.

While the true distribution of the data is not Normal the use of this assumption for the response model in the GAMLSS-based imputation methods is not an unreasonable choice. The main argument in favor is the flexible individual modeling of the mean and variance for each data point. This should alleviate the problems caused by the
departure from a linear model, like the heteroscedasticity. The expectation was not fulfilled, at least with BAMLSS. The performance is worse than in the first experiment with coverage values as low as 0.604 and biased estimation when $R^{2}=0.25$. The most telling indicator of the flaws of this algorithm is the low ratio of the variances. It ranges from 0.426 to 0.877 showing the underestimation of the variance.

In the case of GAMLSS and GAMLSS-JSU the results are good. The only cases of under-coverage are seen when $n=50$, which may be due to the effect of the low sample size on a semi-parametric model. In the case of the chi-squared distributed covariate, the method had the extra obstacle of a different domain for the imputed values. In both experiments the results are valid if $n \geq 200$ although the estimated variances are large. Because of the Johnson's SU distribution allows for the inclusion of skewness and kurtosis in the model is expected that GAMLSS-JSU is the better method of its class and indeed it is.

Table 6.4: Skew normal distribution

### 6.2.3 Uniform and Beta distribution

Figure 6.5 shows an example of the conditions of the fourth and fifth simulation studies. In these two cases, the domain of the predictor variable is limited to the unit interval. The objective of this setting is to test the statistical properties of GAMLSS imputation when the assumed response model has full support.

CCA performs similarly to the Normal case if $X$ is uniformly distributed, with biased and invalid results (cov $\geq 0.578$ ). If $X$ is beta distributed instead, CCA behaves the same way as it did when the covariate was chi-squared or skew normal distributed. This may be, again, an effect of interaction between the shape distribution and the MDM.

Table 6.6 shows that NORM, AMELIA, GAMLSS-JSU and GAMLSS-JSU are the only meaningful methods if $n \geq 200$ when $X$ is uniformly distributed. The estimation results they provide is valid, with the exception of GAMLSS when $R^{2} \geq 0.5$ and $n=$ 200 which has a coverage of 0.925 falling out of the acceptable range. GAMLSSbased methods struggle when $n=50$. The estimation is practically unbiased, but the coverage is between 0.927 and 0.95 .

Table 6.7 displays a not so good outcome for the imputation methods. The depar-

Figure 6.5: Scatter plots of both the direct and reverse regression when the covariate is uniformly between 0 and 1 (top row) of beta distributed (bottom row). The red circles are observed values, and the blue triangles are missing. The coefficient of determination is 0.5 .
ture from normality seems to be too much for NORM and AMELIA which produce biased estimates with coverages between 0.184 and 0.915 . GAMLSS provides valid estimation if $R^{2} \leq 0.5$, when $R^{2}=0.75$ remains unbiased but the coverage drops to 0.935 . GAMLSS-JSU is worse in this scenario, with under-coverage of 0.767 when $n=1000$ and $R^{2}=0.75$. A detailed look at the data that created the table suggests that the problem lies in the imputation of values well below the unit interval. This is mainly related to the support of the Johnson's SU distribution and the fitted values of skewness and kurtosis.

As in the previous simulations when $n=50$ the "self-correcting" property allows methods like MIDAS or PMM-5 to generate coverage values in the acceptable range. From $n=200$ onward, the only interesting method is MIDAS. The method is generally invalid because of under-coverage, but with values which are close to being nominal (cov $\in[0.925,0.935]$ ).

It's less clear in this two experimental conditions which method is better, especially if $X$ is beta distributed. Nevertheless, GAMLSS seems to outperform all other methods as the sample size increases.

### 6.2.4 Poisson

In the sixth experiment, the goal was to test the performance of GAMLSS-based methods when dealing with counted data. The incompletely observed covariate is set to follow a Poisson distribution with three degrees of freedom. In this scenario, not only the support of the response models in GAMLSS and GAMLSS-JSU is different to the true underlying distribution, but it is almost sure all imputed values will be "unrealistic." Figure 6.6 shows an example of the distribution of the missing and observed values under the conditions defined in the experiment.

Figure 6.6: Scatter plots of both the direct and reverse regression when the covariate is Poisson distributed with rate parameter $\lambda=3$. The red circles are observed values, and the blue triangles are missing. The coefficient of determination is 0.5 .

The results in table 6.8 show that NORM, AMELIA and some of the Hot Deck imputation methods are only valid if $n=50$. As the sample size increases, the coverage of these methods falls under the nominal interval. Exceptionally, NORM remains valid if $n=200$. The characteristic behavior of MIDAS, AREG, and PMM is observed too: The bias goes towards 0 while the coverage drops below the acceptable limit.

Only GAMLSS and GAMLSS-JSU are valid if $n=200$ or $n=1000$. Furthermore, GAMLSS-JSU is also valid for $n=50$, which turns it into the best method in this simulation. The flexibility offered by the choice of a Johnson's SU distribution instead of the normal in the GAMLSS works well in this experiment.

Interestingly, CART and RF differ in their performance. They are both invalid but the estimated bias of CART goes to 0 as the sample size increases. On the other hand, the bias of RF actually increases. If $R^{2} \leq 0.5$ and $n=1000$ is between 0.059 and 0.123 .

### 6.2.5 Student's t

The seventh experiment used a $t$ distribution with three degrees of freedom for the incompletely observed variable. De Jong (2012) found that GAMLSS did not perform well if the underlying distribution is heavy-tailed. At that time, however, the imputation method wasn't stable enough to allow for the replacement of the Normal distribution in the response model by a more general one. The current experiment aims to test GAMLSS-JSU in a situation where GAMLSS failed. Figure 6.7 shows the distribution of the observed and missing values and the effects of the MDM.

Figure 6.7: Scatter plots of both the direct and reverse regression when the covariate is $t$ distributed with three degrees of freedom. The red circles are observed values, and the blue triangles are missing. The coefficient of determination is 0.5 .

CCA is invalid with coverage values as low as 0.56 as the sample size increase. This is a consequence of the conditions in the simulation experiment that favored the deletion of values in one tail of the $t$ distributed variable.

The results of the imputation methods are very similar to all other experiments when $n=50$. Beyond this sample size, the performance is dependent on the coefficient of determination. When $R^{2}=0.25$ the imputation methods produce their best estimates for the largest sample size, even if they are generally invalid. This may be caused by the lowest selectivity of the MDM here.

The only two non GAMLSS methods with interesting results are AREG and MIDAS. Both methods are valid or very close to being valid if $R^{2} \geq 0.50$ and $n \geq 200$ with coverage over 0.93 . Strangely if $R^{2}=0.25$ their coverage range from 0.918 to 0.951 , close to methods like NORM or AMELIA.

Both GAMLSS and GAMLSS-JSU failed to provide valid results consistently. They struggle, as expected, with the smallest sample size with coverage between 0.895 and 0.941 if $n=50$. They also suffered from under-coverage when $R^{2}=0.75$ and $n=1000(\operatorname{cov} \in[0.924,0.933])$. In fact, for $n=1000$ GAMLSS is only valid when

$$
R^{2}=0.25
$$

Something to look at is the fact that the imputation results if $n=200$ are better than when $n=1000$. This has been a usual feature of Hot Deck methods, but it was expected that GAMLSS, being a semi-parametric method, improved with larger sample size. A posterior examination of the raw data showed that the problem might be due the position of the missing values. When $n=1000$ there is a higher likelihood of simulating larger values of the $t$ distributed random variable that, if deleted by the MDM, could mislead the predictions of the GAMLSS model.

### 6.3 Multiple Incomplete Predictors

This section presents the outcome of the simulation experiments under the conditions described in section 6.1.2. Three covariates will be incompletely observed. Two are fixed to belong to a Poisson or Binomial distribution. The remaining one will be either Normal, Student's $t$ or chi-square distributed. The performance when only one variable had missing values was explored in the previous section.

The goal in this new set of experimental conditions is to test the robustness and validity of the imputation methods when variables belonging to diverse distributions have to imputed together. By fixing the counted and binary variable while we vary the continuous variable, we want to also assess the impact of misspecified distributional assumptions. The current simulations are an extension to the ones already described by Salfran and Spiess, 2015.

The results of the experiments are summarized similarly as in the previous section. One difference concerning previously presented results is that now the tables are grouped according to the linear regression coefficients estimated: $\beta_{2}, \beta_{3}$ or $\beta_{4}$. This corresponds to the variables incompletely observed, and it will be denoted in the tables. Further, due to computational restrictions, the number of iterations per simulation study is restricted to 500. This changes the interval of acceptable coverage rate to [0.931, 0.969].

### 6.3.1 Normal continuous predictor

Table 6.14 shows the results of using a standard Normal distribution for $X_{2}$, a Poisson with three degrees of freedom for $X_{3}$ and a Binomial with parameter 0.4 for the incompletely observed variables. The reason behind the selection of these probability distributions is only to get a data set that looks more realistic.

The results of COM are valid regardless of the distribution or sample size. As the sample size increases the estimated bias goes to zero, and the ratio of variance oscillate around one while the error decreases. The coverage is always in the acceptable range. This is no surprise since the true model is linear and the estimation is being performed with the full data set. On the other hand, CCA is invalid throughout. The bias is always large and tends to be more or less the same given the distribution of the variable with missing values. The coverage diminishes with increasing sample size. In one instance ( $\beta_{4}$ when $n=50$ ) the problems of CCA are masked by a large estimated error which results in good coverage.

The missing mechanism used deletes aggressively in one region of space with the aim of deliberately stressing the imputation methods. This is more noticeable for the continuous and counted variables, but less so in the binary which has less than $10 \%$ of its values missing. Figure 6.1 shows an example of the distribution of missing and observed values.

In the case of one single predictor with missings, NORM and AMELIA assumed both a Normal distribution for the imputation model. In the current settings, they both still assume a normal distribution when imputing the continuous and counted variables. However, when imputing the binary variable NORM assumes correctly that the distribution is Bernoulli (equation (4.4)) and uses a logistic imputation model. For this reason, it is expected that imputations made with NORM yield acceptable estimation results.

NORM works as expected in the case of $\beta_{2}$ and $\beta_{4}$, using correctly specified models. The inferences are valid concerning the coverage. If $n \leq 200$ the estimator of $\beta_{2}$ is slightly biased and the coverage remains acceptable because of the overestimation in the variance. Nevertheless, the bias disappears as the sample size increases. The estimation of $\beta_{3}$ provides a similar outcome as when imputing a single Poisson variable with missing values. The method is almost unbiased but the coverage goes from valid when $n=50$ to invalid when $n=1000(\operatorname{cov}=0.926)$.

The results of AMELIA are very similar, though the estimation of $\beta_{4}$ is slightly biased even if they have acceptable coverage (bias $\in[-0.071,-0.049]$ ). When $n=50$ there is a tendency to underestimate the true variance of the estimators, at least for the Normal and Poisson covariates. This leads to under-coverage of $\beta_{2}$ if $n=50$.

PMM methods show the same behavior they did when imputing a single variable. The bias of the estimated regression coefficients gets smaller as the sample size increase, given a fixed number of donors and distribution of the covariate. For example, if $k=20$ (PMM-20) the bias of estimating $\beta_{4}$ goes from 0.077 for $n=50$ to 0.001 for $n=1000$. At the same time, the estimated error decreases, but too fast, as indicated by the drop in the ratio between the mean estimated variance and variance over the
simulations. The consequence is that the coverage rate diminishes from generally acceptable values when $n=50$ to values below the limit if $n=1000$. The coverage rate for $\beta_{2}$ and $n=1000$ is less than 0.898 and for $\beta_{3}$ less than 0.924 . The assessment is also true for the estimation of $\beta_{4}$ although the MDM being harmless in this variable allows obtaining valid inference in this instance.

Moving in the other direction, i.e., increasing the number of donors given fixed sample size and distribution of the covariate, there is not monotonicity to the values of bias and coverage. The coverage rate could start from a possibly unacceptable low value, increase up to a maximum, and then decrease again. In the case of the bias, it can get smaller while the number of donors increases and then gets larger again after reaching a maximum value. The main problem with this pattern is that the optimum number of donors doesn't have to be the same for all sample sizes or distributions of the covariate.

The other two Hot Deck methods AREG and MIDAS are slightly better than the other PMM techniques. Of this two MIDAS is almost perfect concerning bias and coverage rate. Except if $X_{2}$ is normally distributed. Then it shows under-coverage when $n=200$ and has a small bias that remains for the largest sample size. AREG, on the other hand, has a smaller bias but it suffers from under-coverage.

The method IRMI uses a different imputation model for the Poisson and Binomial variables. For the Poisson, the model is based on a robust generalized linear regression of Poisson family (Cantoni and Ronchetti, 2001) and for the Binomial on a robust logistic linear regression. This leads to valid or confidence valid coverage rates in the estimation of $\beta_{4}$ and $\beta_{3}$ (if $n \leq 200$ ). Nevertheless, the estimation is extremely biased for all sample sizes. This is more noticeable in the estimation of $\beta_{2}$ with an absolute bias larger or equal than -0.698 , when the true value of the parameter is 1.5 . The bias invalidates the inference due to its large values. Again, the reason for this severe ill performance may be caused by the wrong classification of data points as outliers.

If $n=50$, IRMI masks the biased estimation by a large overestimation of the variance with a ratio between 1.23 and 1.77. With increasing sample size the error decreases, leaving the ratio and bias more or less the same. This generates extreme values of under-coverage. When $n=1000$ the coverage of $\beta_{2}$ and $\beta_{3}$ is 0 and 0.440 respectively.

The two Recursive Partitioning methods perform very differently from each other. RF performs as bad as IRMI with only a little less bias to its favor. The coverage can be as low as 0.011 for $\beta_{2}$ if $n=1000$. Next CART is better than RF when estimating $\beta_{2}$ and $\beta_{3}$, but it is worse due to bias with under-coverage for $\beta_{4}$. In general, CART-based estimators seem to be biased, with the bias decreasing for larger sample sizes. The problem seems to be the underestimation of the error variance, as seen in the low
ratio, that leads to invalid coverages.
The GAMLSS-based methods assumed a Bernoulli distribution for the imputation model of $X_{4}$, exactly like NORM. This is handled via the mice() function's arguments. BAMLSS appears to be deficient, with a similar outcome as in the previous simulations. It shows no bias or a very small one, but it systematically underestimates the variance of the estimators. The only acceptable result is in the relatively harmless case of imputing the Binomial with $n=1000$. On the contrary, both GAMLSS and GAMLSS-JSU show good results most of the time: vanishing bias with increasing sample size and nominal coverage rates. The exception is GAMLSS when $n \leq 200$ which shows coverage of 0.912 and 0.925 .

Table 6.10: Results for the estimation of $\beta_{2}, \beta_{3}$ and $\beta_{4}$ in model 6.4. The imputed covariate $x_{2}$ follows normal distribution.

### 6.3.2 Non-Normal Predictors

The next experimental conditions tested kept fixed the distributions of $X_{3}$ and $X_{4}$, albeit with different regression coefficients in model (6.4). Instead, $X_{2}$ is set to be either the Student's t or Chi-squared distributed. By using this design, we intended to modify the shape of the data cloud by either introducing extreme values or asymmetries. Table 6.11 shows the result of estimating the regression coefficients of model (6.4) when $X_{2}$ is t distributed.

The results are very similar to the case where $X_{2}$ is normal with some obvious exceptions. NORM and AMELIA fail to properly estimate $\beta_{2}$. AMELIA has a small bias and good coverage when $n=50$. Besides that particular case, both methods generate increasingly worse coverage rates while the sample size increases (cov $\leq 0.914$ if $n=1000$ ).

All other methods perform as they did in the previous experiments. The estimation of $\beta_{4}$ is mostly fine with all methods yielding valid or confidence valid coverage rates, with the exception of CCA and BAMLSS. The biases become increasingly smaller, although for CCA, AMELIA, IRMI, RF, and BAMLSS the bias increases from $n=200$ to $n=1000$.

The estimated values of PMM methods keep their usual tendency of vanishing bias and higher precision at the expense of lower coverage rate. It gets to the point where no PMM is valid for $\beta_{2}$ if $n \geq 200$ and none for $\beta_{3}$ if $n=1000$. AREG performs close to the parametric PMM methods. Furthermore, there is always a better PMM method than AREG. The only promising Hot Deck method seems to be again MIDAS with valid estimation of $\beta_{3}$ (in addition to $\beta_{4}$ ) but it fails to be valid for $\beta_{2}$.

Inference based on IRMI is horrible, especially if $n=1000$. The bias of the estimator of $\beta_{2}$ is -0.446 with coverage rate of $0 . \mathrm{RF}$ is not far behind with an absolute bias of -0.402 and coverage rate of 0.019 . CART is biased for $\beta_{2}$ and $\beta_{4}$ but practically unbiased for $\beta_{3}$. Nevertheless, it suffers from under-coverage. Even so, as a consequence of the overestimated variance, the three methods are valid or confidence valid concerning coverage if $n=50$.

GAMLSS is not valid for $\beta_{2}$ if $n \leq 200$, but together with GAMLSS-JSU are the only two valid imputation methods if $n=1000$ for all variables with missings. GAMLSS-JSU has 0 bias for $\beta_{2}$ and $\beta_{4}$ if $n=1000$ with nominal coverage, and only a bias of 0.014 for $\beta_{3}$, still with nominal coverage.

Table 6.12 shows the results of the estimation of $\beta_{2}$ when $X_{2}$ is chi-squared distributed. The simulation results related to $\beta_{3}$ and $\beta_{4}$ showed very similar results as when $X_{2}$ is normal or t distributed, and led to the same conclusions. The table was split and the results for $\beta_{3}$ and $\beta_{4}$ are presented in appendix B.

There are some differences between the estimation of $\beta_{2}$ in this latest experiment. CCA is still invalid, but the coverage is even better than the rest of the imputation methods (with the exceptions of MIDAS, GAMLSS, and GAMLSS-JSU). In general all methods show a slight to moderate increase of the bias with an associated drop in coverage rates.

GAMLSS and GAMLSS-JSU are the only methods that provide valid inference when $n=1000$ for all regression coefficients. When $n \leq 200$ one or both can show lower than acceptable coverage rates. Also GAMLSS-JSU is markedly biased for $\beta_{2}$ and $\beta_{3}$ if $n \leq 200$.

Table 6.11: Results for the estimation of $\beta_{2}, \beta_{3}$ and $\beta_{4}$ in model 6.4 when the imputed covariate follows a Student's $t$ with three degrees of freedom.

### 6.3.3 Weak MDM

Table 6.13 shows the results of estimating $\beta_{2}$ in in model (6.4) under all three simulated conditions using the weak MDM. The results for $\beta_{3}$ and $\beta_{4}$ are presented in appendix B.

Under the weak MDM, the difference between classes of missingness is very small. This translates into a mechanism which is almost MCAR. The lower selectivity cause some instances of CCA to be valid, in particular if $X_{2}$ is $t$ or chi-squared distributed. When $X_{2}$ is normally distributed, CCA is biased with coverage rates between 0.924 and 0.93 .

In the case where $X_{2}$ is normally distributed, all methods except IRMI, CART, RF and BAMLSS provide valid estimators of the three linear regression coefficients. When $X_{2}$ is $t$ or chi-squared distributed, most of the imputation methods that were valid in the first experiment still provide valid inference in general, but some coverage rates fall below the acceptable range. For example, PMM-20 or PMM-D have a coverage rate of 0.93 if $n=1000$ and $X_{2}$ is chi-squared distributed. GAMLSS and GAMLSS-JSU suffer from over-coverage if $X_{2}$ is $t$ distributed.

As a rule, the weak MDM allows the imputation methods to systematically produce valid or confidence valid results. In some cases the coverage falls below the nominal confidence interval but it's not extremely low. This does not applies to IRMI or RF, although their bias is less in comparison to the strong MDM, is still large and the coverage rates are very low.

Table 6.13: Results for the estimation of $\beta_{2}$ in model 6.4 when the imputed covariate follows a Normal, Student's t or Chi-squared distribution, the last two with three degrees of freedom. Weak MDM.

### 6.3.4 Non-monotone MDM

To address the task of imputing a multivariate set with non-monotone missing patterns mice implements the Fully Conditional Specification algorithm (Section 3.5.2). Van Buuren and Groothuis-Oudshoorn (2011) suggested that a low number of iterations would be enough. In the simulations the number of iterations is set to the default value of the function mice() which is five. The results of AMELIA, IRMI, and AREG are omitted since they are oblivious the problems caused by non-monotone missing patterns (see Rubin, 1987, Section 5.6). Due to the poor performance in all previous simulation experiments BAMLSS is also removed from further computations.

Table 6.14 provides the results of estimating $\beta_{2}$ in in model (6.4) when the continuous incompletely observed variable in the multivariate data set was set to be normal, $t$ or chi-squared distributed. The MDM is non-monotone and very selective. The results for $\beta_{3}$ and $\beta_{4}$ are presented in appendix B.

If $X_{2}$ is normally distributed the results of the experiment are similar to the monotone case. NORM, PMM-1, MIDAS, GAMLSS, and GAMLSS-JSU provide valid inference under the specified condition.

Once $X_{2}$ is changed to be $t$ or chi-squared distributed, the results of the methods in the mice library remain stable concerning the estimated biases and coverage rates. Due to the poor performance in all previous simulation experiments BAMLSS is also removed from further computations. The GAMLSS-based imputation methods, which in all previous simulations were valid or confidence valid, show coverage rates between 0.686 and 0.874 . GAMLSS-JSU has an estimated bias of -0.233 if $X_{2}$ is chi-squared distributed.

The results of the application of the weak non-monotone MDM don't provide any new insight in the performance of the imputation methods. The same conclusions as in the weak monotone counterpart applied to this simulations. There is only a small deviation to the results and is the performance of the GAMLSS-based methods. GAMLSS and GAMLSS-JSU show the same estimation problems as in the strong non-monotone MDM case if $X_{2}$ is $t$ or chi-squared distributed.

Table 6.14: Results for the estimation of $\beta_{2}$ in model 6.4 when the imputed covariate follows a Normal, Student's t or Chi-squared distribution, the last two with three degrees of freedom. Strong non-monotone MDM.

## Chapter 7

## Conclusion \& Summary

The first half of the current contribution provides an introduction to the missing data problem and multiple imputation method. In Chapter 2 the problem was defined. The basic theory of Multiple Imputation is presented in Chapter 3. These two chapters give an overview of the foundation of MI and should help any interested reader to understand the main ideas concerning the topic. Also useful for practitioners is Chapter 4. This chapter summarizes in a clear way a wide range of imputation algorithms.

The second half of the dissertation focus on the research goals. Chapters 5 and 6 presented the theory and the experimental results of the GAMLSS-based imputation methods. The following sections discuss the achievement of the research objectives.

### 7.1 Research Goals

### 7.1.1 Relaxation of the assumptions of GAMLSS-based imputation models

The first objective was the relaxation of the distributional assumption of the error within the GAMLSS imputation method to distributions with unknown mean, variance, skewness, and kurtosis.

Due to computational restrictions, when de Jong (2012) developed presented the GAMLSS imputation method based on the model given by equation (5.1) and Algorithm 8, the distribution in the imputation model was almost always set to be normal. In other cases, the algorithm often failed if a family distributions more complex than the normal were used for the error term of the semi-parametric model.

Section 5.2 explained that the imputation algorithm is not dependent on the distribution assumed, i.e., the justification for the method does not change if a different distribution is used. This fact moved the solution to the software implementation of
the method. The R library ImputeRobust was developed to address the software instabilities (Salfran and Spiess, 2018a,b). Sections 5.3 and 5.4 described the details of the implementation and how to use the software.

The software is stable and became available to the public in 2017 (Salfran and Spiess, 2018a). It has been shown to work with distributions like the Student's $t$ with three parameters and Johnson's SU, with four. Any distribution available to the gamlss library is also available to ImputeRobust. Furthermore, the published software is an add-on to the mice library (van Buuren and Groothuis-Oudshoorn, 2011). Users have the option to use GAMLSS-based imputation methods from within mice itself.

Alternatively, a parallel method to GAMLSS was also developed. It is based on the MCMC sampling of the Bayesian posterior distribution of the model. The method attempts to reduce the number of fitting steps of the original GAMLSS imputation algorithm. The implementation is also described in Section 5.2, and it is available in the ImputeRobust library. Not all distributions provided by gamlss can be used, but it is possible to assume a normal or Johnson's SU distribution.

### 7.1.2 Imputation of multiple incompletely observed variables

The second objective was to extend the GAMLSS-based imputation methods to the multivariate case and evaluate them concerning the validity of parameter estimators of scientific interest.

De Jong (2012) already showed that GAMLSS-based imputation produces valid results when imputing one variable with missing values in several experimental conditions. He also proposed to integrate the algorithm with mice, but it was not realized. Furthermore, the imputation algorithm was never tested in combination with the Fully Conditional Specification method.

The extension of the imputation methods to the multivariate case is accomplished with the ImputeRobust library. The mice package takes care of pre-processing the incomplete multivariate data set and then uses the FCS methodology and the functions included in ImputeRobust to impute the missing values. The software design decision of using mice was made to reach a broader user base for the GAMLSS-based imputation methods.

The results in Section 6.2 support the statistical validity of GAMLSS-based methods when imputing single variables with MAR values and from a wide range of probability distributions. In particular, the method GAMLSS-JSU, which uses a Johnson's SU distribution for the imputation model, displayed to be valid or confidence valid if the sample size was at least 200 in all experiments related to one variable with missing values. These results imputing a single variable are essential since the FCS algorithm
will transform the problem of imputing $k$ incompletely observed variables into $k$ problems of imputing a single variable with missing values. The simulation results for small data sets $(n=50)$ showed that MI with semi-parametric GAMLSS could result in small non zero estimated bias and under-coverage of the true parameter.

Section 6.3 presents the results of the simulation experiments that were defined to test the validity of the GAMLSS-based imputation of multiple incompletely observed variables simultaneously. The results show that GAMLSS-JSU was the only imputation method that produced valid results if $n=1000$ given that the MDM is monotone or the continuous variable with missing values was normally distributed.

The results are less convincing if the continuous variable is $t$ or chi-squared distributed and the MDM is non-monotone. Even so, the performance of the GAMLSSbased methods seemed to improve with the increasing sample size. The failure to reach statistical validity may be overcome by increasing the sample size. Another point of attention could be the number of iterations of the Gibbs sampler in the mice function. The results use the default amount of iterations which is 5. GAMLSS-based imputation methods may require more iterations for the Gibbs sampler to get closer to the stationary distribution.

Regardless of the issues with the non-monotone MDM, the parameter estimation in the single predictor case and with monotone patterns was always acceptable. The simulation experiments are not a mathematical proof for the statistical validity of imputation methods based on GAMLSS. However, the simulation results give evidence supporting the statistical validity.

### 7.1.3 Comparison of the Imputation Methods

The third objective was to perform an extensive empirical study that compared the GAMLSS-based imputation methods and available modern techniques via simulation experiments.

Simulation studies were performed modifying the number of variables with missings, their distribution and the selectivity of MAR mechanisms. Sections 6.2, 6.3 and Appendix B show the results of these experiments. The GAMLSS-based imputation methods were compared to all methods described in Chapter 4. In general, the results favor the use of GAMLSS using a Johnson's SU distribution over the remaining parametric, semi- and nonparametric imputation methods.

The results support the "self-correcting" property of MI (Little and Rubin, 2002; Rubin, 1987, 1996, 2003) for the smallest sample size tested ( $n=50$ ). In general, this means an acceptable coverage rate, with a bias hidden by the over-estimated variance. As the sample size increases, the "self-correcting" property seems not to be
able to adjust the systematic underestimation of the variance.
The Bayesian linear regression and Amelia methods allowed valid inferences when the imputation model was correctly specified. However, these two methods led to invalid inferences with biased estimations and low coverage rates when the distribution of the DGP was not normal.

Other approaches like the hot deck methods were less sensible to variations of the underlying distributions. Nevertheless, the simulations show that techniques based on a given number of donors like PMM suffer from structural problems which are easier to detect in large samples. As the sample size increases, the estimated bias moves towards zero, but the estimated error decreases too fast and PMM present coverage rates below acceptable limits. The nonparametric method aregImpute does not show the same trend as PMM but still leads to invalid inference. Midastouch is the hot deck method that looks more promising, especially with multivariate data sets, but more often than not leads to invalid inference when $n=1000$.

Concerning IRMI, the results show that an imputation method that automatically identifying "outliers" is a terrible idea. If an MDM creates sparsely populated regions in the observed sample space, values in that region will be treated as outliers and imputations could introduce a systematic bias in the estimation.

The estimation based on recursive partitioning methods can be biased or not depending on the distribution of the incompletely observed variables. Still, even when the methods are unbiased, they both lead to invalid inference due to under-coverage.

Finally, the results based on GAMLSS are very good if the Bootstrap predictive distribution is used to generate the imputations (Algorithm 8). The technique allows valid inferences in most scenarios presented in the current dissertation, especially if a flexible distribution like the Johnson's SU is used in the imputation model. However, in small samples, it may lead to biased estimators, which may be due to the semi-parametric nature of the models. On the contrary, results based on the Bayesian posterior (Algorithm 9) were unsatisfactory, the inference was generally invalid.

### 7.2 Recommendations

Mathematical proof of the validity of MI results is difficult to obtain due to the analytical complexity of the missing data problem. Empirical studies exploring the inferential validity can be used, but especial attention should be given to the criteria used to evaluate the performance. The required goal for any imputation method is to provide statistically valid results. This means that simulations studies should always look at the estimated bias and coverage of imputation methods.

One aspect that is often neglected is that the validity of estimation results could
depend on the strength of the MDM. A very selective mechanism could cause the thinning out of certain regions in the sample space with ill consequences for the imputation techniques. It may be helpful to examine the distribution of observed and imputed values graphically.

Based on the simulation results, users of imputation methods in real applications should avoid blindly using available functions, including the ones provided by ImputeRobust. Some R libraries like mice or VIM provide diagnostics plots to explore the results of multiply imputing missing values. The choice over which method is the most appropriate based on a graphical representation may not be enough.

The source of the bad performance of GAMLSS-based methods with non-monotone missing patterns is still unknown. Further simulation studies or large-sample results could be needed to find an answer. On the other hand, the imputation algorithm is considerably slower than available standard methods. Since ImputeRobust is published under the GPL-3 license, users with the technical skills can contribute to the improvement and optimization of the code.

The proposed method BAMLSS proved ineffective. Even so, the basic idea of using MCMC sampling to simulate the Bayesian posterior is appealing. If the estimation problem is solved, the method could be more efficient than plain GAMLSS. Sampling with MCMC is still costly, but software implementation of MCMC can be made faster than the backfitting algorithm of GAMLSS.

## Appendix A

## $R$ code for the example

Data generating process:

```
> set.seed(19394)
> n <- 500
> mu <- rep(0, 4)
