Dekan des Fachbereichs Geowissenschaften

## **PREAMBLE**

Some of the most important problems and questions focussed on in this thesis were identified by field experiments performed within a major project initiated and carried out by several groups.

The investigations, as well as the resulting enhancements presented here are mainly reactions attributed to campaign observations. Therefore the newly designed sampling system, the ground reference unit and the sophisticated investigation strategy have arisen as means to an end – and were not the intended purposes of this study. To accomplish the findings a particular venture was the critical scrutiny and the adaptation of established assumptions.

Since the data acquisition was carried out within the restricting frame of the main project specific experiments were only possible in a limited fashion. More flights would have been desirable, also because the amount of data obtained from the field campaigns is low.

As a corollary, the result of this study is not a register with regional carbon 'numbers', but a list with aspects and impairments which have to be taken into account, providing the basis for further investigations focussing on airborne and ground based assessment of the carbon budget.

In spite of, or thanks to the adverse conditions, new findings and ideas could be deduced which shall be applied in succeeding projects.

*'And therefore as a stranger give it welcome ...'*

## 1. INTRODUCTION

As soon as mankind appeared on the scene some hundred thousand years ago it formed its environment. But during the last few hundred years the human impact became more and more distinct, because of the broadening and intensification which came along with the growth of population and the increase of the living standards and economic demands.

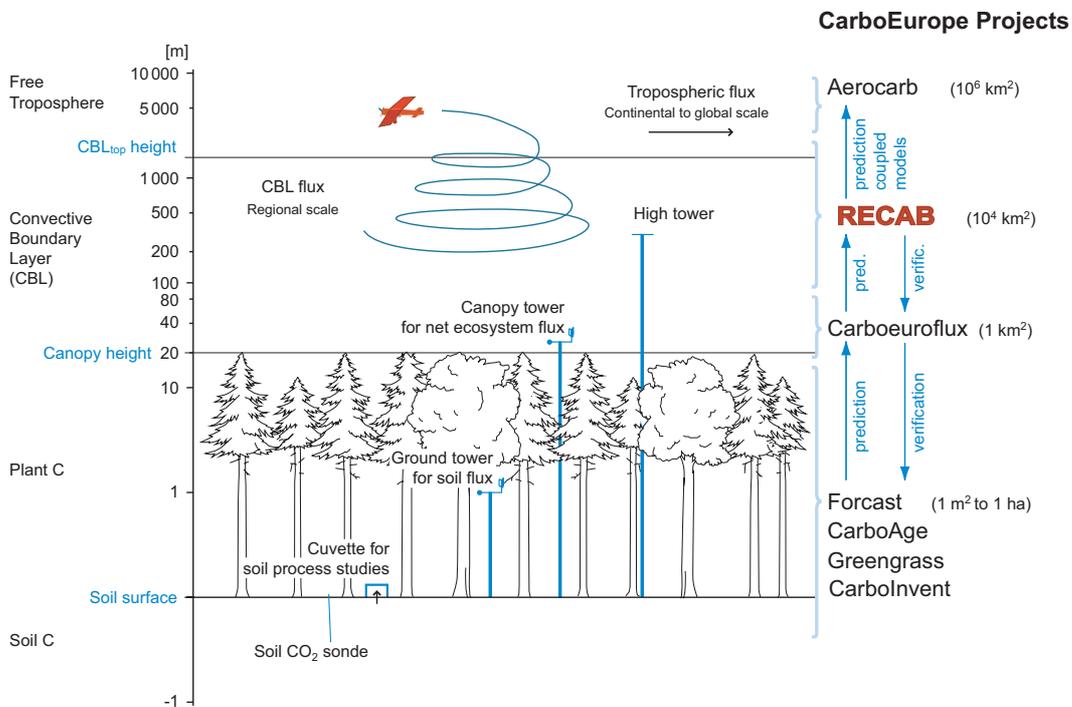

These anthropogenic interferences are influencing not only the terrestrial surface but also the atmosphere. Effects, which became apparent during the last two decades, are for example the ozone hole, the acid rain and the summer smog phenomena, and more recently the 'additional greenhouse effect', which appears to provoke the rising of the global mean air temperature. A close relationship between observed temperature rise and the surge of the CO<sub>2</sub> release since the era of the 'industrial revolution' is being discussed. The rise of CO<sub>2</sub> concentration is resulting in particular from the increasing consumption of fossil fuels and from land use changes. An interdisciplinary assessment body was established with the *Intergovernmental Panel on Climate Change (IPCC)* in 1988, to provide basic information for policymakers on the status quo and for future scenarios of impacts and economics of climate change. The Kyoto Protocol manifested in 1997 the political efforts to react on the interferences with the climate system. More scientific investigations were initiated, among others the *CarboEurope* cluster.

As one part of the cluster the project *RECAB (Regional Assessment and Monitoring of the Carbon Balance within Europe)* focused on the link between local investigations and global modelling strategies [HUTJES ed. 2003]. Eleven groups from seven European countries cooperate since the summer of 2000 to improve theories and strategies and to develop new methods, with the aim to determine the carbon budget on regional scales by a close link between experimental and theoretical approaches.

One fundamental part of the project was the provision of data. During several field campaigns, of two to four weeks duration, flight and ground based data collections were conducted at different locations within Europe over the year. The *Max-Planck-Institut für Biogeochemie (MPI-BGC)* contributed with airborne studies within the lower troposphere to the project, supplementing ground level

measurements. The experimental concept based on the theory of the *CBL*- (convective boundary layer) *Budget-Approach* [LAUBACH AND FRITSCH 2002] should provide by comparison of repeated measurements information about the flux of carbon within the study region. To supply a data base for such task, air samples were taken in different heights and analysed for trace gas mixing ratios and for the composition of the stable isotopes in CO<sub>2</sub>. Aim of this flask sampling was to

- distinguish between the contributions from anthropogenic sources and natural sources and sinks and to
- estimate carbon budgets for small regions ( $\leq 10^4 \text{ km}^2$ ).

**Figure 1.** The RECAB project within the frame of the CarboEurope cluster. (from FREIBAUER 2002, modified)

However, after the analysis of the first measurements it became obvious, that fundamental theoretical and conceptual aspects might be affected in a crucial way by processes which had not been taken into account so far.

Hence the emphasis of this thesis became

- the identification and characterisation of these impairments and

- the evaluation of the potential of multiple trace gas and isotope analyses for
  - the construction of an improved sampling system,
  - the development of a new investigation strategy
  - the characterisation of the RECAB study regions and their comparison.

Regarding this study the RECAB project occupies an ambivalent position. On one hand the field campaigns were the base for the data acquisition. On the other hand, due to the constraints fixed in the primary concept, specific experiments could only be accomplished in a restricted frame.

The structure of this thesis: An introduction into the theoretical base and the methods used is given in the first section. Subsequently, the laboratory- and test flight experiments are discussed that were performed before and during the RECAB field campaigns. To concentrate the technical aspects in one block also the new flight sampling system is examined, quasi in an anticipation of the findings from the field experiments.

The field observations are presented with respect to the development of instrumentation and measurement strategy in chronological order. Regarding the aim of the RECAB project – the characterisation and comparison of the study regions - the interpretation of the results is according to regions.

The potential of multiple tracer studies is reflected with respect to the characterisation and the comparison of the RECAB regions, followed by a discussion of more general theoretical and conceptual aspects. Finally an enhanced investigation strategy is presented.

In the conclusion section the significance of the findings and the perspectives of airborne studies regarding flask sampling and multiple tracer analyses are discussed.

Flight campaigns and ground sampling data are recorded on the attached CD-ROM. In addition, a photo documentation of the sampling equipment and of the study sites gives an impression of the campaign performance.

## 2. BASIC PRINCIPLES: THEORY AND EXPERIMENTAL SETUP

### 2.1. Theory

#### 2.1.1.1. Long lived trace gases in the atmosphere

Carbon is a common component found in several compounds of the atmosphere, such as carbon dioxide (CO<sub>2</sub>), carbon monoxide (CO), methane (CH<sub>4</sub>) and the group of the volatile organic compounds (VOCs), but also in form of solid particles. For the estimation of the budget direct concentration measurements but also the examination of the variations of all carbonaceous constituents would be necessary. Since a full C-budget was not anticipated within the RECAB project the project focussed on the investigation of the most common atmospheric species with global warming potentials (CO<sub>2</sub>, CH<sub>4</sub>, later extended by CO).

In the atmosphere the gases are characterised by different mixing ratios as also by different contribution potentials to the greenhouse effect. The *absolute* amount of the individual gas species is thereby highly variable in time and space. Major causes are the distribution of sources and sinks on the land surface, as well as parameters which dominate biological and chemical activity, like temperature, radiation, the availability of potential reaction partners, and the synoptic weather pattern.

Furthermore information can be obtained from the *relative* ratios of the gases. On one hand the covariance provides information on chemical reaction chains, e.g. H<sub>2</sub> and CO, because they are involved in the oxidation of CH<sub>4</sub>. On the other hand, in particular from non reactive constituents, evidence for air mass change can be derived. As such a tracer SF<sub>6</sub> was included in the analysis scheme.

The occurrence of trace gases in the atmosphere is mainly dependent on three factors: a) the nature of the sinks and sources, b) their magnitude and persistence as well as c) their distribution [MAHRT 1997]. Often the generating and destructing mechanisms, defining the lifetime of a species, are coupled to biological and chemical activities, expressed in diurnal and annual cycles, but also the availability depends on nutrients or reaction partners. It might thus happen that a sink becomes a source and vice versa. Urban and rural environments, as point and

area sources are affecting the mixing ratio field of trace gases, which are additionally modified by topography and circulation.

Causes for the omnipresence of a gas species might be a uniform distribution of the sources and/or a long residence time. Characteristic for such species are concentrations barely differing from site to site.

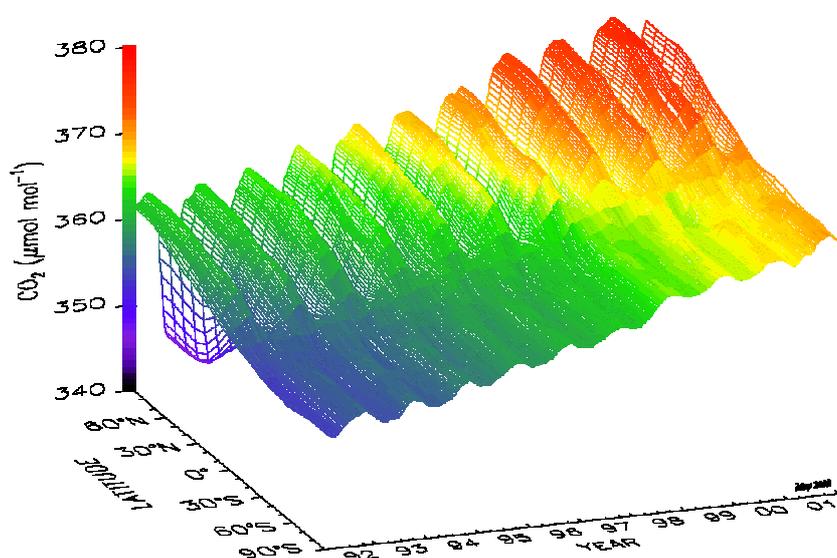

A long life time is necessary to use an individual species as a tracer, for example due to air mass exchange. As a nearly purely anthropogenic gas species, which is also chemically rather inert without sinks at the surface or in the troposphere, SF<sub>6</sub> was chosen during the study.

### *CARBON DIOXIDE CO<sub>2</sub>*

Of all analyzed gas species CO<sub>2</sub> is the one which occurs with the highest mixing ratio and shows the most distinct periodicity. For the year 2000 the global average of the volume mixing ratio was calculated to be 368 ppmv [HOUGHTON et al. 2001], with higher absolute values and a larger seasonal variation in the northern hemisphere. This is related to the fact that the strongest sources and sinks are located on the northern hemisphere continents [CIAIS et al. 1995, PRENTICE et al. 2000]. While the uptake of CO<sub>2</sub> by vegetation or oceans occurs over large areas, the major part of the anthropogenic CO<sub>2</sub> is released from point sources, like cities and industrial complexes. The long life time of 50 to 200 years [U.S. GREENHOUSE GAS INVENTORY PROGRAM 2002] is the main cause for the observed average concentration increase indicated in figure 2.2.

Most significant terrestrial sources are the respiration of autotrophic and heterotrophic organisms, and the combustion of organic material, especially the use of fossil fuels, by traffic, industry and households [WITTENBERG et al. 1998, ANDRES et al. 1999, LANGENFELDS et al. 2002]. Since the beginning of the industrial revolution the average atmospheric volume mixing ratio of CO<sub>2</sub> increased by about 30% from 280 ppm to the actual value [HOUGHTON et al. 2001]. Assimilation of CO<sub>2</sub> by plants is the major terrestrial sink. Depending on the organism, whether annual or persistent, the storage time may vary from a growing season to centuries. However, a part of the carbon is recycled immediately by respiration. Driven by plant activity a diurnal and an annual cycle can be

distinguished, where the contribution of the uptake exceeds the release of CO<sub>2</sub> during the growing season – which can be divided in an assimilation uptake during day time and a respiration release during night time. In dormant seasons, such as winter time respiration is in general dominant [RANDERSON et al. 1997, WINSTON et al. 1997, RAYNER & LAW 1999]. Because of the covariance of radiation and temperature with the development of the boundary layer depths, the stable nocturnal layer is characterised by high CO<sub>2</sub> mixing ratios. Whereas in the CBL the mixing ratio is depleted because of the extension of the layer depths - and during the growing season plant uptake.

**Figure 2.1.** Latitudinal distribution of atmospheric carbon dioxide mixing ratio in the marine boundary layer air. The surface represents data smoothed in time and latitude, from the NOAA / CMDL cooperative air sampling network (PI: P. Tans and T. Conway, NOAA / CMDL)

The terrestrial stocks of natural carbon are estimated to be 1500 Pg in soils and 500 Pg in plants [IPCC 2001]. The atmospheric reservoir contains about 730 Pg, whereby the flux between atmosphere and land is estimated to be around 122 PgC/a and from the land to the atmosphere to be about 120 PgC/a [HOUGHTON et al. 2001]. In total the carbon-pool of the oceans (39000 Pg) exceeds the terrestrial sinks by more than a factor 50, the assumed natural influx into the ocean is calculated to be 90 Pg per year. Human perturbation adds an annual flux of 5.4 PgC/a from geological reservoirs (5.3 PgC/a from fossil fuel burning,

0.1 PgC/a from cement production) to the atmosphere. A net uptake by land of 1.9 PgC/a is nearly balanced by a release of 1.7 PgC/a from land use changes. The ocean net uptake is estimated to be 1.9 PgC/a.

Besides for CO<sub>2</sub> the air samples were also analyzed for the mixing ratios of five additional trace gases. Two carbonaceous compounds, CO and CH<sub>4</sub>, and N<sub>2</sub>O, SF<sub>6</sub> as well as H<sub>2</sub> also are having a direct or indirect greenhouse warming potential. Additional information can be obtained from the ratios of the individual species when back tracking the air masses with the aim to identify the sources origin.

#### *CARBON MONOXIDE CO*

Formation processes and the occurrence of CO in the atmosphere are described by many studies [NOVELLI et al. 1992, NOVELLI et al. 1994, BAKWIN et al. 1994, NOVELLI et al. 1998, BERGAMASCHI et al. 2000, WOTAWA et al. 2001]. A main source of CO are combustion processes [LAURSEN et al. 1992, KATO et al. 1999, WARNECK 2000, ANDREAE & MERLET 2001]. Different materials and burning temperatures lead to characteristic CO to CO<sub>2</sub> ratios in emissions, for example the volume percentage ratio of CO / CO<sub>2</sub> from biomass burning of forest wild fires is 11 – 25 %, for burning of agricultural wastes 3 – 16 % or for burning of wood 6 – 18 %. In the smoldering stage CO emission can, depending on the temperature, rise up to 80 % [WARNECK 2000]. Characteristic ratios emitted by car engines are estimated to be between 0.02 – 1.34 %. Typical values for power plants are 0.03 % and for industrial production processes 2.15 %. Distinctly higher rates are obtained for emissions from metal production 71.2 % (ranges calculated from data published by the KRAFTFAHRT-BUNDESAMT 2003 and by the UMWELTBUNDESAMT 2003). CO can therefore be used as a tracer for CO<sub>2</sub> from combustion processes.

On the other hand CO is a direct precursor of CO<sub>2</sub>. The reaction of CO with the OH radical, the major sink process for carbon monoxide, leads to CO<sub>2</sub> [ATKINSON 1989, BLAKE et al. 1993, TYLER et al. 1997, RÖCKMANN et al. 1998]. Thus, the ratio

of CO / CO<sub>2</sub> changes with the distance from the source and the concentration of OH radicals.

There are two reaction cycles (net equations [2.1.2.6. and 2.1.2.10.]), depending on whether NO<sub>x</sub> is available or not. Beside the role of NO<sub>x</sub> as a catalyst for the formation of O<sub>3</sub> its presence is also important for the regeneration of OH radicals.

Or if the NO<sub>x</sub> concentration is low:

Another sink, however less important than the reaction with the hydroxyl radicals, is the microbiological uptake in soils. The sources of CO are, with nearly equal amounts, fossil fuel combustion and related activities, biomass burning, the oxidation of CH<sub>4</sub> (see below [2.1.2.11. – 2.1.2.16.]) and the oxidation of natural hydrocarbons [CONWAY et al. 1994, WARNECK 2000].

Since the late 1980s a decrease of the CO mixing ratio can be observed because the actual sink strength exceeds source strength [HOUGHTON et al. 2001].

**Table 2.1: The Global and North Hemispheric Budget of Carbon Monoxide in the Troposphere (Tg CO per year)<sup>1)</sup>**

1) from Warneck (2000)

#### *METHANE CH<sub>4</sub>*

In air samples the highest volume mixing ratios following CO<sub>2</sub> are found for CH<sub>4</sub>. Sources of CH<sub>4</sub> are wetlands, rice paddies, landfills and ruminants [THOM et al. 1993, ETHERIDGE et al. 1998, KUHLMANN et al. 1998, SASS et al. 1999, WALTER et al. 2000, WALTER et al. 2001b]. Because of the formation by mostly biological activity a clear annual cycle for CH<sub>4</sub> can be observed.

Major sink for CH<sub>4</sub> is the oxidation by OH radicals via formaldehyde (HCHO) to CO and H<sub>2</sub> [ATKINSON 1994, TYLER et al. 1997].

The net reaction equation describes the formation of one molecule CO, four molecules ozone and two molecules hydroxyl radicals (and of water) per methane molecule, in an environment characterised by NO<sub>x</sub> concentrations above a threshold of about 5 – 10 ppt [GRAEDEL & CRUTZEN 1993].

#### *HYDROGEN H<sub>2</sub>*

For the formation of hydrogen in general similar processes as for CO are important: mainly the oxidation of CH<sub>4</sub> [2.1.2.15a] and of non methane hydrocarbons (NMHCs), as well as combustion [NOVELLI et al. 1999, BARNES et al. 2003].

The major sink for H<sub>2</sub> is the uptake by soils, with a minimum in winter and a maximum in early autumn. Another sink, but less important, is the reaction of H<sub>2</sub> with OH radicals, forming H<sub>2</sub>O and H.

In the literature no information about the pre industrial concentration of H<sub>2</sub> could be found, but since the formation processes are comparable to the production paths of CO also an increase since the beginning of the industrial revolution might be expected.

*NITROUS OXIDE N<sub>2</sub>O*

Major sources for N<sub>2</sub>O are losses from soils during denitrification and nitrification processes [SCHMIDT et al. 1988, MEIXNER et al. 2000]. Since the nitrogen conversion is due to microbiological activity under both aerobic (nitrification) and anaerobic (denitrification) conditions, seasonal variations are occurring because of a strong temperature and humidity dependence. On account of the introduction of artificial fertilizers and their increased use the global mean mixing ratio of N<sub>2</sub>O is rising as well [DOBBIE et al. 1999, RÖCKMANN et al. 2003]. There are no known sinks of N<sub>2</sub>O in the troposphere, removal occurs only by transport to and photochemical destruction in the stratosphere.

**Table 2.2: Tropospheric Budget of Nitrous Oxide (Tg per year)<sup>1)</sup>**

1) from Warneck (2000)

## SULPHUR HEXAFLUORIDE SF<sub>6</sub>

Anthropogenic emissions are accounting nearly completely for the origin of SF<sub>6</sub>. Major sources are releases through leakages of insulation glass and tire fillings, exhalations from aluminium production and high voltage plants. Less than 1% is of radiochemical origin, released from the geosphere [HAASE 1999]. SF<sub>6</sub> is chemically inert and no sinks are known for the troposphere, therefore it can be used within this study as the most probable tracer with regard to anthropogenic emissions and air mass changes [MAISS et al. 1994, MAISS et al. 1996].

**Table 2.3: Characterisation of the Atmospheric Trace Gases<sup>1</sup>**

### 2.1.1.2. Isotopic Signatures in Carbon Dioxide

Because of the active discrimination by vegetation characteristic signatures can be found in the surrounding atmosphere and the plant material itself [LLOYD et al. 1996, EHLERINGER et al. 1997, FLANAGAN & EHLERINGER 1998]. Thus, stable isotopes can be used to distinguish and estimate the contribution of different sources of spatially and temporally varying quantities like CO<sub>2</sub> [TRUMBORE 1999]. By the implementation of isotope analyses a differentiation between contributions by the vegetation and by the insertion of anthropogenic material might be achieved [CIAIS et al. 1995, ZONDERVAN & MEIJER 1996, BAKWIN et al. 1998, YAKIR et al. 2000].

Isotopes are nuclides of a chemical element, which have equal atomic numbers but differ by the number of neutrons, the nucleon number. In CO<sub>2</sub> several stable isotopomers can be found, e.g. C<sup>12</sup>O<sup>16</sup>O<sup>16</sup>, C<sup>13</sup>O<sup>16</sup>O<sup>16</sup>, C<sup>13</sup>O<sup>18</sup>O<sup>16</sup>, C<sup>13</sup>O<sup>18</sup>O<sup>18</sup>, C<sup>12</sup>O<sup>16</sup>O<sup>18</sup>, C<sup>12</sup>O<sup>18</sup>O<sup>18</sup>. Here the CO<sub>2</sub> of the sampled air was analyzed for delta<sup>13</sup>C and delta<sup>18</sup>O [WERNER et al. 2001], whereby the focus is on the carbon isotopes. The data are expressed in the common delta nomenclature, expressing the relative deviation of the sample <sup>13</sup>C/<sup>12</sup>C ratio from a reference isotopic ratio in per mill [‰]:

$$\delta^{13}\text{C} [\text{‰}]_{\text{V-PDB}} = (R_{\text{sample}} / R_{\text{V-PDB}} - 1) \cdot 1000 \quad [2.1.1.2.1.]$$

Primary international standards are the V-PDB (Vienna PeeDeeBelemnite) for delta<sup>13</sup>C and the V-SMOW (Vienna Standard Mean Ocean Water) for delta<sup>18</sup>O.

#### CARBON ISOTOPES

When building up organic material plants consume CO<sub>2</sub> and release O<sub>2</sub>. The gas exchange takes place through the stomata and can (mostly) actively be regulated by a more or less wide opening of these pores. Since the period of the highest photosynthetic activity around noon comes along with the decrease of relative humidity and thus an increase in drought stress different strategies of adaptation have been developed during evolution. Due to specific assimilation strategies three classes of plants can be distinguished: C<sub>3</sub>, C<sub>4</sub> and CAM (with a crassulacean

acid metabolism). Most of the plant species, like bushes and trees, are belonging to the C<sub>3</sub> type, where in the group of the C<sub>4</sub> class grasses are most prominent. CAM plants are specifically adapted to semiarid / arid conditions.

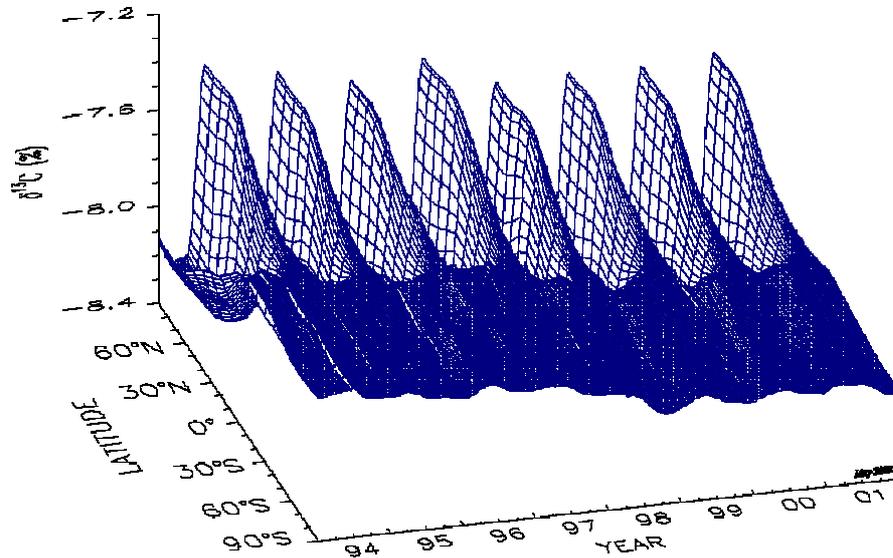

Under normal conditions plants tend to assimilate the lighter CO<sub>2</sub> molecules easier than the ones containing the heavier <sup>13</sup>C isotope. By this discrimination the ratio of the carbon isotopes, compared to the original air, changes. Plants contain more of the <sup>12</sup>C isotope, whereas the concentration of the heavier <sup>13</sup>C isotope increases in the ambient air [FARQUHAR 1989, LLOYD & FARQUHAR 1994, FLANAGAN ET AL. 1996, FLANAGAN & EHLERINGER 1998]. Because the discrimination against <sup>13</sup>C is much higher for C<sub>3</sub> than for C<sub>4</sub> plants, delta<sup>13</sup>C values in biomass are -20 to -35 ‰ and -9 to -14 ‰ for C<sub>3</sub> and C<sub>4</sub>, respectively [EHLERINGER & RUNDEL 1989]. But also ambient air will show a plant related isotope ratio. A less negative delta<sup>13</sup>C value indicates the assimilation rate of the plants [TROLIER et al. 1996, TRUDINGER et al. 1999]. On the other hand respired air from plants is depleted in <sup>13</sup>C relative to the atmospheric CO<sub>2</sub>, which leads to a dilution resulting in a more negative delta<sup>13</sup>C value [LEVIN et al. 1995, FUNG et al. 1997, KAPLAN et al. 2002].

Baseline air has a delta<sup>13</sup>C value about -8 ‰ and possesses a seasonal cycle with a peak to peak amplitude of 0.05 ‰ at the South Pole and 0.8 ‰ at high northern latitudes.

Fossil organic material reflects the isotopic signature of the original plant substance, mostly C<sub>3</sub> vegetation. Depending on the kind of fuel and the formation process further differentiations can be made [TANS 1989]. Natural gas contains a high amount of CH<sub>4</sub> which can be highly depleted in <sup>13</sup>C [HOEFS 1996]. CO<sub>2</sub> from oxidation processes reflects the isotopic ratios from the source substances [BOSINGER et al. 1988, BERGAMASCHI et al. 1998]. Under diagenic conditions, characterised by high pressure and temperature, additional alterations may occur, for example during the formation of coal and lignite.

Isotopic ratios of atmospheric air vary on different time scales. Beside the diurnal cycle there is also a seasonal variation, due to changes of the assimilation activity [BUCHMANN et al. 1996, FLANAGAN et al. 1999]. The activity of the soil organisms, which are recycling plant material, is affected by temperature and humidity [CIAIS et al. 1999]. Likewise the contribution of anthropogenic emissions, especially from fossil fuel consumption, reflects seasonality.

The actual annual decline rate is around 0.025 ‰ (see figure 2.2. and [<http://www.cmdl.noaa.gov/ccgg/figures/co2c13rug.jpg>]).

**Figure 2.2.** Latitudinal distribution of the carbon isotopic composition of atmospheric carbon dioxide concentration in the marine boundary layer air. The surface represents data smoothed in time and latitude from the NOAA / CMDL cooperative air sampling network analyzed at the University of Colorado INSTAAR (PI: J. White, NOAA / CMDL)

For  $^{13}\text{C}$  a direct relationship is given with the  $\text{CO}_2$  gas mixing ratio: A reduction of the  $\text{CO}_2$  mixing ratio with a simultaneous enrichment in  $^{13}\text{C}$  indicates an uptake by vegetation, whereas an increase of the  $\text{CO}_2$  mixing ratio and a depletion of  $^{13}\text{C}$  can be attributed to the consumption of organic material.

The 'Keeling plot approach' is commonly used for the determination of the carbon isotope composition of the source. It is assumed that a measured air sample mixing ratio  $C_m$  is the sum of an atmospheric background  $C_b$  and a contribution from an individual source or sink  $C_s$ .

$$C_m = C_b + C_s \quad [2.1.1.2.2.]$$

and for the isotopic ratio respectively

$$\delta_m C_m = \delta_b C_b + \delta_s C_s \quad [2.1.1.2.3.]$$

The background should be represented by the tropospheric  $\delta^{13}\text{C}$  ratio (at least by the global average; -8‰), the ground source/sink is characterised by its specific carbon isotope discrimination behaviour. This discrimination can be calculated from the intercept of the linear regression between the carbon isotope ratios and the inverse of the  $\text{CO}_2$  mixing ratio [KEELING 1958, PATAKI et al. 2003], described by the equation

$$\delta_m = \delta_s + \frac{1}{C_m} \cdot M \quad \text{with} \quad [M = C_b(\delta_b - \delta_s)] \quad [2.1.1.2.4.]$$

where  $\delta_m$  is the isotopic value and  $C_m$  the measured  $\text{CO}_2$  mixing ratio. The subscript b denotes the background value, s respectively the source signal.

#### OXYGEN ISOTOPES

Also the  $\delta^{18}\text{O}$  in  $\text{CO}_2$  was determined. Even if the focus of this study was not on the oxygen isotopic ratios a brief introduction shall be given for the sake of completeness.

Changes of  $\delta^{18}\text{O}$  in atmospheric  $\text{CO}_2$  are induced by plants, similar to the carbon isotopes. Thereby three different sources have to be distinguished: oxygen from soil water taken up by the plants, oxygen that exchanges with the  $\text{CO}_2$  of the ambient air, and  $\text{CO}_2$  from the photorespiration.

In the water cycle a discrimination of the heavier water molecules exists during evaporation, which leads in a first step to an  $^{18}\text{O}$ -depletion in the water vapour. During the formation of precipitation more  $^{18}\text{O}$  condenses, hence the remaining water vapour becomes lighter, whereas the  $\delta^{18}\text{O}$  of the cloud water increases during ageing [CIAIS et al. 1997]. When the plants are taking up the soil water no discrimination occurs, but through reduced evaporation of the  $\text{H}_2^{18}\text{O}$  compared to  $\text{H}_2^{16}\text{O}$  a relative accumulation of  $^{18}\text{O}$  takes place in the leaf water.

Atmospheric  $\text{CO}_2$  enters the plants through the stomata. Hereby the uptake is restricted on one hand by a diffusive kinetic isotope effect, on the other hand only a few of the oxygen atoms are fixed via photosynthesis [FLANAGAN et al. 1997]. The majority are leaving the plants again, but some of them have exchanged in an

equilibrium reaction with atoms of the relative enriched leaf water. Both effects are leading to a relative increase of  $\delta^{18}\text{O}$  in the ambient atmospheric  $\text{CO}_2$ . Contrary to this,  $\text{CO}_2$  from respiration is more characterised by the signal of the soil or precipitation water, which results in lower  $\delta^{18}\text{O}$  values [FARQUHAR et al. 1993]. Isotope discrimination in plant metabolism occurs during biosynthesis of carbohydrates and other primary or secondary products; e.g. STERNBERG [1989] describes for cellulose oxygen isotope ratios to be 27‰ ( $\pm 3\%$ ) higher relative to leaf water. Caused by further kinetic and equilibrium isotopic effects the  $\delta^{18}\text{O}$  ratio decreases for secondary products; total plant dry matter has a  $\delta^{18}\text{O}$  value of about 18‰ [YAKIR 1998].  $\text{C}_3$  and  $\text{C}_4$  plants differ in  $\delta^{18}\text{O}$  in the organic material. Since  $\text{C}_3$  plants are, compared to  $\text{C}_4$  species, more sensitive to water stress assimilation via photosynthesis is only active when no vapour pressure deficit occurs, leading to a relative low  $^{18}\text{O}$  fraction in the leaf water [STERNBERG 1989].

Because of the isotope fractionation processes during evaporation and condensation  $\delta^{18}\text{O}$  varies also on spatial scales [PEYLIN et al. 1999]. Due to the increasing depletion in  $^{18}\text{O}$  inland areas reflecting continentality. Also specific environmental conditions, like the low evaporation rate in higher latitudes, are provoking characteristic isotopic signals. By the enhanced oxygen isotope ratios in organic material relative to water at the site of synthesis (as described by STERNBERG to be about 27‰) environmental conditions during the assimilation period can be obtained also from the plant material, as practised for example by palaeo-climatic studies via the analysis of tree rings [BURK & STUIVER 1981].

An example for zonal differentiations can be obtained when focus on higher latitudes.

In addition to the plant activity, also soil respired  $^{18}\text{O}$  is contributing to the  $\delta^{18}\text{O}$  ratio of the atmospheric  $\text{CO}_2$ . Therefore estimates of this rate have to be taken into account when calculating the fraction of plant activity [MILLER et al. 1999].

Reasons for neglecting  $\delta^{18}\text{O}$  for the estimates within this study were: Oxygen isotopes are very sensitive with respect to alterations, in particular for interactions with water and surface processes during the sampling and the transport / storage of the flasks [GEMERY et al. 1996]. One crucial uncertainty, but still not verified,

might be provoked by the drying unit. However, the main reason for dropping a detailed investigation of  $\delta^{18}\text{O}$  was caused by the fact that the real vegetation signal was unduly affected and masked by interferences (as described in the more detailed presentation of the findings).

### 2.1.2. RECAB Strategy

The main objective of RECAB (Regional Assessment and Monitoring of the Carbon Balance within Europe) was the development of methodologies and techniques to qualify and quantify the carbon budget on regional scales [HUTJES ed. 2003]. This goal should be achieved by the linkage of experimental investigations and modelling studies, combining bottom-up with top-down approaches. The bottom-up attempt should be pursued by local tower measurements and profile flights. Information for the top-down part should come from model calculations and also from profile flights, which therefore connect both concepts.

Part of the MPI-BGC was to collect data by vertical profile flights within the lower part of the atmosphere for estimations of the carbon fluxes, the determination of source and sink processes and the provision of data for the modelling groups.

A primary aim of RECAB was to acquire data from characteristic regions within Europe, whereby a region was defined as an area of typical appearance and a spatial extension of roughly  $10^4 \text{ km}^2$  (100 x 100 km). An intention was also to carry out the campaigns in zones with different climatic and vegetation conditions, at least once during summer and winter time. Additionally the investigations should be performed at places where information would be available also from local measurements.

Both, the study regions and the time frame, where and when the data acquisitions should take place, had been specified by the principal investigators of RECAB at the beginning of the project. Because of tower measurements operational within the regions, five field sites were defined: *Uppland* in Sweden, the central part of The Netherlands – both regions including one tall tower site (Norunda in Sweden, Cabauw in the Netherlands). At the study areas *Thuringia* in Germany, *Valencia* in Spain and *Lazio* in Italy several small towers are operational.

Beside the rough classification into three zonal districts (Northern, Central and Southern Europe) a further longitudinal differentiation was an intention of the project, regarding the sites in Central Europe between the region in The

Netherlands and the more continental site in Germany. In Thuringia additional flights were performed between fall 2000 and spring 2001.

**Figure 2.3. RECAB study regions**

The square sizes are scaled to the defined extension of the 'region' ( $\leq 10^4 \text{ km}^2$ ).

(Picture from DFD: <http://www.caf.dlr.de/caf/satellitendaten/bildergalerie/>)

The importance of RECAB for this study is given by two aspects: Data were acquired during the field campaigns, which also provided (in a constricted frame) the opportunity for specific experiments. On the other hand, the field studies had to serve primarily the aims and the time schedule of RECAB, which meant rather a constraint.

Focus of this study are the analyses of flask samples with respect to information on composition and trace gas mixing ratios ( $\text{CO}_2$ ,  $\text{CH}_4$ ,  $\text{N}_2\text{O}$ , additionally  $\text{CO}$ ,  $\text{H}_2$  and  $\text{SF}_6$  since August 2001) as well as on stable isotopes in  $\text{CO}_2$ . Through the multiple tracer studies specific carbon sources and sinks should be identifiable. This primary contribution to the project was enhanced by additional investigations, helping the RECAB strategy to link bottom-up and top-down approaches: Development of a ground reference and sampling unit, adaptation of the flight strategy and modelling studies for specific flights.

## Field Campaigns

During two to four weeks several intensive combined flight- and ground based investigations were performed on selected days. The local partners led the coordination of the different combined investigations.

Measurements were performed continuously at meteorological and flux towers, whereas the low level horizontal flux transects, using the *mobile flux plane* 'Sky Arrow' (abbreviated 'MFP'), and the vertical CBL-profile flights were carried out as frequently as possible, weather permitting.

The activities included:

- CBL vertical profile flights with flask sampling and continuous measurements (part of the MPI-BGC; for observed parameter and system configuration see chapter 2.2.1); additional ground reference sampling and measurements (using the new implemented mobile mast; see chapters 2.2.1.3. & 5.2.1.)
- Horizontal transect flights with high frequency measurements (CO<sub>2</sub> mixing ratio and water vapour by an open-path infrared gas analyzer, as well as air temperature, pressure, radiation, 3D-wind field) by the MFP [for detailed description of instrumentation see GIOLI et al. 2004]
- Continuous eddy-covariance measurements and recording of meteorological parameter from local towers
- Tethered balloon (Valencia) and SODAR profiles (The Netherlands) for wind profile observation and the determination of the CBL top height
- Data processing and submission to the 'Carbis' data base
- Forward and inverse modelling of the individual campaigns

Flight activity was limited by the fixed budget for the operational costs, maintenance intervals of the MFP and the number of the sampling flasks.

Because the MPI-BGC does not possess its own aircraft a plane had to be hired at each site. Therefore the equipment had to be adapted to the individual configurations at each air field (see also the documentation of the 'Flask Sampling Unit' on the CD-ROM).

**Table 2.4. Nomenclature of the study regions and basic data describing the measurement campaigns**

<b>Region</b>	<b>Coordinates<sup>1</sup></b>	<b>Land Type</b>	<b>Period<sup>2</sup></b>
<b>Valencia</b> (Spain)	39°15'N 00°30'W	southern coastal zone; very intensive agriculture, Valencia urban area	<b>17.06.-07.07.2001</b> 16.11.-15.12.2001
<b>Uppland</b> (Sweden)	60°10'N 17°50'E	Nordic coniferous forest and wetlands; extensive agriculture, rural structure	<b>11.08.-09.09.2001</b>
<b>The Netherlands</b>	52°10'N 05°40'E	very intensive agriculture, high level of urban sprawl	14.01.-10.02.2002 <b>10.07.-28.07.2002</b>
<b>Lazio</b> (Italy)	42°25'N 11°55'E	southern plains; forests and agriculture, urban character	27.05.-27.06.2002
<b>Thuringia</b> (Germany)	51°05'N 10°30'E	very intensive agriculture within the basin, ridges covered by forests, scattered villages and cities	20.10.-23.10.2000 13.01.-17.01.2001 10.02.-16.02.2001 09.05.-11.05.2001 <b>15.07.-02.08.2001</b> <b>06.08.-16.08.2002</b>

Also the sampling sites and the flight patterns had to be specified. In addition characteristic field sites had to be selected and the ground reference unit had to be installed. Ground level flask sampling was mostly carried out, due to the lack of man power, before or after the flights, whereas the meteorological measurements are available for mostly the whole period.

#### *FLIGHT OPERATION*

Measurement flights were executed at least twice per day. The first or morning flight was scheduled to take place around one hour after sunrise, in order to sample an average of the regional respiration signal. To record a clear signal of the plant activity the second flight was scheduled around the maximum assimilation rate. Flask sampling was carried out at four to five pre-defined levels within the boundary layer and at one height clearly above the inversion. Thereby

<sup>1</sup> Central / main point of the study region

<sup>2</sup> Summer campaigns (bold)

the vertical profile had to reach a maximum height of about 3000 m above ground, depending on the thermal conditions. Oriented at ground reference points the flight pattern enclosed a quadratic air column with a typical leg length of 2 km, realized by GPS guidance.

For system comparisons, and to obtain further information, also intermittent flights with the 'Sky Arrow' were performed.

Because airborne measurements are highly depending on weather conditions the decision whether to fly or not had to be made spontaneously in the early morning of the scheduled flight days. In addition, the flight were affected by fixed operational hours of the airfields, restrictions caused by local flight regulations, the availability of pilots and aircraft capability.

#### *GROUND REFERENCES*

Reference samples were taken over characteristic land units within the study region. On one hand the prevalent conditions should be recorded and samples be taken simultaneously with the airborne measurements. On the other hand we aimed to collect data from the individual sites for different microclimatic situations. Therefore the sensor mast was erected at the characteristic field sites for defined periods and shifted between them. Flask sampling was performed at five heights (0.1, 0.5, and 1.0, 2.0 and 5.0 m above ground) at least once for each site, twice a day. 'Night time measurements' had to be accomplished around sunrise, to gain a clear respiratory signal. The day time sampling, reflecting assimilation, was executed in the early afternoon.

Additional mapping of the environment was performed with specific focus on the vegetation (kind, composition, distribution and status of development), the geomorphic appearance (soils, topography, exposition) and with respect to anthropogenic influences like buildings, obstacles, and intensive utilisation – in particular fertilization, animal stocks, harvest and tillage.

**Table 2.5. Nomenclature and land use character of the study sites**

Region	Ground Reference Sites	Land Use Character	Flight Profile Location
Thuringia (Germany)	Hainich	beech forest	Hainich
		agricultural utilisation	Gebesee
Valencia (Spain)	Rice	rice fields	Rice
	Orchard	citrus and apricot plantations	Orchard
	Macchia	quasi natural shrubland	Macchia
		Mediterranean Sea	Mare
	Highway	main road	
Uppland (Sweden)		coniferous forest	Norunda
	Florarna Swamp	open wetland	Florarna
	Forest	mixed forest	
The Netherlands	Loobos	coniferous forest	
	Maize	agricultural utilisation	Maize
	Marshland	grassland	Cabauw
		mixed forest	Forest
Lazio (Italy)	Roccarespampani	deciduous forest	
		deciduous forest surrounded by agricultural land	Tuscania
	Orvinio Meadow	grassland	Orvinio
Valley	forested mountain slope		

Coloured are the sites where only ground or flight investigations were performed. For a more detailed description of each study location see the individual campaign folders on the CD-ROM.

All campaigns were documented in a uniform scheme. Data gained from the continuous systems were logged and frequently saved on hard disks. The flight- and ground operations were recorded in specific forms. Sketches and photographs, in particular aerial views, were prepared to record the environmental conditions during the investigations. Plant material was sampled and dried. A detailed depiction of all activities was kept in a campaign diary.

### 2.1.3. Convective Boundary Layer

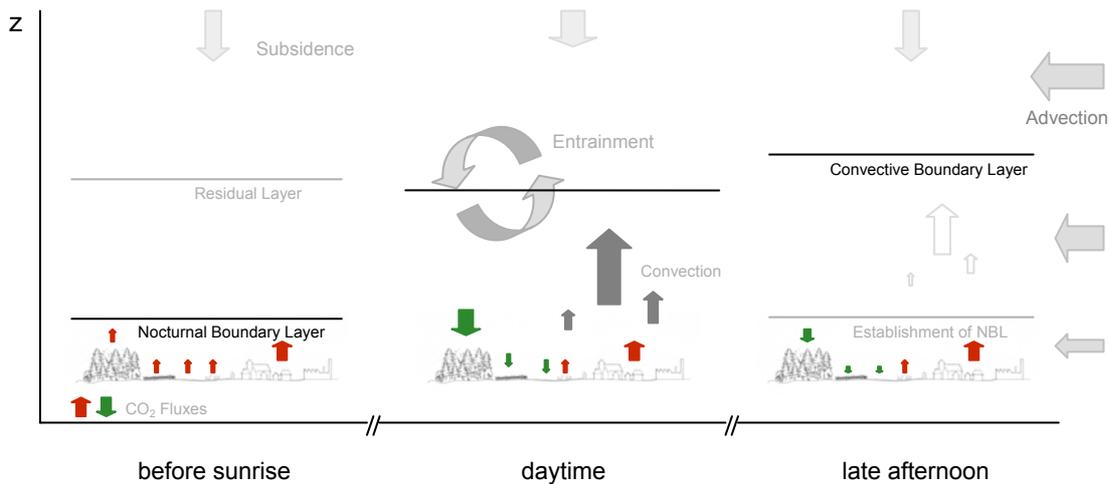

During the last years several theoretical studies have proposed the idea to use the atmospheric boundary layer for the description of larger areas [KLAASSEN 1992, RAUPACH et al. 1993, RAUPACH 1995, RAUPACH & FINNIGAN 1996, RAUPACH 1998, DENMEAD et al. 1996, CLEUGH 1998].

Based on this approach several scientific groups started to investigate parameters, such as energy fluxes or fluxes of climatic relevant trace gases, by aircraft measurements on larger scales [CRAWFORD et al. 1996, LANGENFELDS et al. 1996, DESJARDINS et al. 1997, NAKAZAWA et al. 1997, LLOYD et al. 2001, LEVIN et al. 2002, LLOYD et al. 2002, RAMONET et al. 2002]. These investigations were performed over wide-stretched areas of homogeneous character, such as in Siberia or the Amazonian Basin. Part of this study will be therefore to focus also on answering the question if and to what extent a transfer of the approach will be possible to areas with differing conditions, in particular with a mosaic of different surface characteristics.

The boundary layer can be defined *'as that part of the troposphere that is directly influenced by the presence of the earth's surface, and responds to surface forcings with a timescale of about an hour or less'* [STULL 1988, p.2].

Characteristic for the convective boundary layer is its strong diurnal development, with different behaviours depending on the surface conditions [SHUTTLEWORTH 1988, DE WEKKER 1995]. The typical height of the boundary layer top varies between 100 and 3000 m, forced in particular by solar irradiance. Thereby the shallow night time 'stable boundary layer' (NBL), growing during day time because of thermal convection, converts into the 'convective boundary layer' (CBL). During this expansion the air that had been trapped during the night, characterised by high mixing ratios of CO<sub>2</sub> from plant respiration for example, is modified by entrainment of air from the 'residual layer' located above the NBL. Further contribution occurs by vertical motion on synoptic scales, like subsidence in high pressure systems, and by horizontal advection [LEHNING 1996, SAMUELSSON & TJERNSTROM 1999].

Based on this concept a budget approach was developed using the CBL as an ‘integration chamber’ for monitoring larger areas. It can be characterised in a simplified manner: if mass conservation can be assumed and the fluxes through the walls and the top of the air column are known, it should be possible to calculate surface-atmosphere exchange rates from the variation of the amount of scalars inside the air column.

**Figure 2.4.** Scheme of the CO<sub>2</sub> fluxes and of the CBL behaviour on a summer day, showing CBL development from a nocturnal / stable boundary layer until the establishment of the next night time boundary layer.

#### ‘CBL-BUDGET APPROACH’

The CBL-budget concept was already practised from small aircrafts for studies carried out by the MPI-BGC over Siberia and the Amazon Basin [LLOYD et al. 2001]. It was the objective within RECAB to utilise the budget approach for the determination of CO<sub>2</sub> fluxes in a similar way.

However, here the role of the ‘CBL-budget approach’ is not well defined by its application. Since serious questions about fundamental assumptions arose from the flask sampling observations, general conceptual aspects became the most import topic.

A detailed specification of the ‘CBL budget approach’ theory is given by LAUBACH & FRITSCH [2002]. The aim of the concept is the explanation of the surface fluxes

( $F_s^G$ ) by the measured change in the CBL content from two profiles ( $dN/dt = F_s^C$ ) and estimates of the fluxes from the top and the sides of the CBL: Entrainment ( $F_s^E$ ), Subsidence ( $F_s^S$ ) and horizontal advection ( $F_s^H$ ).

$$F_s^G = F_s^C - F_s^E - F_s^S - F_s^H \quad [2.1.3.1.]$$

The time integral can be expressed respectively

$$I_s^G = I_s^C - I_s^E - I_s^S - I_s^H \quad [2.1.3.2.]$$

Basic for the calculation is the scalar conservation equation, which is integrated from the ground to the top of the CBL column, leading finally to [2.1.3.3.]

$$I_s^G = \alpha_s \left\{ \underbrace{\left[ \langle \rho \rangle_i z_i \langle s \rangle_i \right]_{t_1}^{t_2}}_{I_s^C} - \underbrace{\int_{t_1}^{t_2} \langle s \rangle_i \frac{\partial}{\partial t} (\langle \rho \rangle_i z_i) dt}_{I_s^E} - \underbrace{\int_{t_1}^{t_2} \rho_+ (s_+ - \langle s \rangle_i) \frac{\partial z_i}{\partial t} dt + \int_{t_1}^{t_2} \rho_+ (s_+ - \langle s \rangle_i) w_+ dt}_{I_s^S} \right\}$$

Horizontal advection is neglected

For the application several assumptions have to be made, inter alia 1) constant vertical gradients of the scalars and the vertical wind component in z and t, 2) linearity of the CBL growth and 3) linearity regarding the trend of the scalar changes in t.

**Table 2.6. Nomenclature used in the equations**

Roman letters	Greek symbols	Operators	Subscripts
$M$ mass per surface area of the air column	$\Delta s$ drawdown difference of $s$ at $Z = Z_{top}$	$\langle \dots \rangle_h$ vertical average from $Z = 0$ to $Z = Z_{top}$	$+$ just above $Z = Z_i$
$s$ mixing ratio	$\alpha s$ conversion factor		$top$ at $Z = Z_{top}$
$t$ time	$\rho$ air density		$1, 2$ time, respect. flight count
$w$ vertical wind component			
$z_i$ CBL height			

LAUBACH & FRITSCH presented additionally a second, so called 'fixed-mass column' approach. Since mass conservation is required changes of the scalars within the entire column are including already the entrainment flux ( $I_s^C - I_s^E$ ).

Regarding the subsidence term a linear time dependency has to be assumed for the drawdown gradient.

Similar to the CBL column approach horizontal advection is neglected. From these the cumulative surface flux is expressed as:

$$I_s^G = \alpha_s \left\{ \underbrace{M_{top} (\langle s \rangle_{top_2} - \langle s \rangle_{top_1})}_{I_s^C - I_s^E} + \frac{1}{2} w_{top} \rho_{top} (\Delta s_2 + \Delta s_1) (t_2 - t_1) \right\} \quad [2.1.3.4]$$

----- $I_s^S$ -----

In principle the strategy can be divided into three parts: a) the estimation of the boundary layer top height for each profile, by analysis of the potential temperature  $\theta$  and the humidity  $f$  gradients, b) the calculation of the amounts contributed by the fluxes through the walls and the top of the column within the time step and c) the determination of the scalar fluxes from the residual of the mixing ratio change.

The utilisation of the ‘CBL-budget approach’ for the determination of CO<sub>2</sub> fluxes could not be achieved in this study, since general questions regarding the concept arose from the flask sampling observations.

Another attempt to estimate surface fluxes focuses on a ‘Lagrangian’ concept. By a field experiment carried out in June 2001 above a forest in south-western France, loosely associated to the RECAB project, the potential was evaluated [SCHMITGEN et al. 2004]. A brief discussion of this experimental approach will be given when introducing finally the enhanced investigation strategy, derived from the multiple tracer and isotope analyses, in chapter 5.4.

#### 2.1.4. Ground Characterisation and References

Most of the processes affect the CO<sub>2</sub> concentration in air samples, as the majority of the sources and sinks are related to or located at the ground. Also atmospheric dynamics are coupled to the surface, like turbulence driven by thermal inhomogeneity, the formation of eddies and the horizontal air flow influenced by the topography [LEHNING 1996, SCHMID & LLOYD 1999]. Therefore the incorporation of ground reference information is a fundamental requirement.

To get the basic information about the composition of the trace gases and of their individual mixing ratios and isotope signature, investigations were performed directly at ground level. Since the variations are affected by the individual source and sink characteristics, whose variability is mostly driven by climatic parameters, records of the climatic conditions have to be performed for the most prominent landscapes of the study regions. Around this 'ground reference sites' also detailed investigations were carried out with regard to the kind of vegetation, its extension and distribution.

High productivity of plants is linked in particular to temperature, humidity and radiation and the complex interplay of these factors. Because of the missing solar irradiance during night time the photosynthetic activity stops and the vegetation respire  $\text{CO}_2$ . A reduction of the uptake (or even a change from a  $\text{CO}_2$  sink into a source) can also occur during day time under favorable radiation conditions, provoked for example by drought stress. The incidence of air pollutants, like ozone, or the infestation by herbivores can likewise provoke rapid perturbations.

Heterotrophic organisms, which are respiring organic material in the soils, also require specific optimal conditions. In frozen, as well as in dry soil the activity is reduced to a minimum. Variability occurs also in subjection due to the supply of organic material or decomposition products. Furthermore some of the organisms need aerobic, others, like the methanogenic bacteria, anaerobic conditions. The pathways of the disintegration can change with the time, for example depending on the oscillation of the water table, which has to be taken into account especially for wetland regions.

In particular temperature and irradiance are of interest with respect to the situation and the development of the boundary layer. Also information about wind velocity and direction are mandatory for an estimation of transport and mixing processes.

### **2.1.5. Combined Investigations**

#### **2.1.5.1. Modelling Approaches – Inverse Studies**

Intention for the implementation of a transport model within this study was to obtain further information for quality estimations, in particular with regard to contaminations, and to determine the origin of the sampled air. In cooperation with

CHRISTIAN RÖDENBECK from the modelling group of the MPI-BGC, analyses were performed for several flights of the SPA<sup>13</sup>CE experiment (see chapter 4.2.8.). The sensitivities were calculated using the global 3D atmospheric tracer transport model TM3 with the vfg grid (192 x 96 L28) configuration [HEIMANN & KÖRNER 2003, RÖDENBECK 2003], driven by observed meteorology [NCEP reanalysis, [www.ncep.noaa.gov](http://www.ncep.noaa.gov)]. By the implementation of diverse specific inventories (EDGAR data base for fossil fuel) and model results (BiomBGC for biosphere influence) individual spatial contribution probabilities were calculated. Estimates of the 'regional footprint' were performed by the comparison with the interpretation results of the gas and isotope analysis. In addition the model could be tested using real data with respect to some specific sensitivities.

Further calculations were carried out in cooperation with GORKA PÉREZ-LANDA, from the RECAB partner CEAM in Valencia, for individual study sites in Spain and Italy. Our intention was to identify the spatial origin and to derive by comparisons and interpretation of the sampled data the probable formation process.

The simulation was performed with the non-hydrostatic PSU/NCAR Mesoscale Model MM5, combined with the Lagrangian Particle Dispersion (LPD) model FLEXPART. Data assimilation was applied with NCEP reanalyses. To enhance the resolution within the surroundings of the study areas nested-grid configurations were used with 130 x 130 and 202 x 301 grid cells at 27 and 9 km grid size, respectively, centred over the Western Mediterranean Basin [PÉREZ-LANDA et al. 2002].

To obtain quick information with respect to tendencies of the origin and the pathway of the sampled air masses additional back trajectory calculations were performed. One motivation therefore was to improve the interpretation of the free troposphere samples from the Italian mountain site with their specific gas composition (see chapter 4.2.3).

The calculations were performed using the back trajectory particle model 'HYSPLIT' (HYbrid Single-Particle Lagrangian Integrated Trajectory, Version 4) developed by NOAA and Australia's Bureau of Meteorology [DRAXLER & HESS 2002]. A fixed number of particles are tracked backwards from the receiving point, which are assumed to be advected by the mean wind field, but

taking also a turbulent component into account. The calculations were driven by the observed meteorology from the NCEP reanalyses, running in one hourly time-steps for a period of 14 days. Horizontal resolution of the model is adapted to the grid system of the meteorological data. The internal model heights above ground level can be determined at any interval; the top height was defined to be 9000 m.

An introduction to back trajectory calculations was given by MANUEL GLOOR (MPI-BGC), who also made the model available for these studies.

#### 2.1.5.2. Land Use Classification

Europe is characterised by a nearly complete anthropogenic landscape. Thus a patchy surface is formed by the heterogeneous distribution of urban agglomerations, agriculturally used areas, managed forests, water spaces and a few unmanaged smaller parts. Even at the scale of the individual study region a homogenous distribution of the sources and sinks can not be expected. In consequence, an inventory of the different land use classes, within the region and extended to the areas affecting the study space, is required to provide the basic information with respect to the interpretation of the air samples.

A land use classification, using remote sensing data from the Landsat ETM+ sensor (path 194 / row 24), was performed within the frame of a diploma thesis study [REITHMEIER 2003]. The area covered by a scene encloses a square with a leg length of roughly 185 km, at a spatial resolution of 30 x 30 m. Since the classification was not finished in time only a first draft could be used for this study. Nevertheless, by the implementation of the remote sensing based land use classifications additional information about the spatial distribution of the individual sources and sinks became available. Primary intention was to obtain a tool for the verification of the findings from the 'regional' measurements. Therefore data should be derived from the spatial percentages of the classified areas (as presented in table 2.8.), related to their characteristic gas composition and isotopic signatures. The focus should be on the differentiation of forested lands, agricultural areas and urban settlements, deduced from satellite images for the campaign periods at the Hainich site in 2001 and 2002.

For the analyses the images, already radiometrically and systematically precorrected (*Level 1G* data from NASA's Earth Observing System [<http://edcimswww.cr.usgs.gov>]), have been further processed with respect to geometric and atmospheric corrections. Additionally cloud-covered pixels were identified and excluded for the subsequent land use classification. For the identification of training areas additional spectral transformations were performed prior to the classifications with the standard maximum likelihood classifier of the image processing software *ENVI® Version 3.5* (see figure 2.5.).

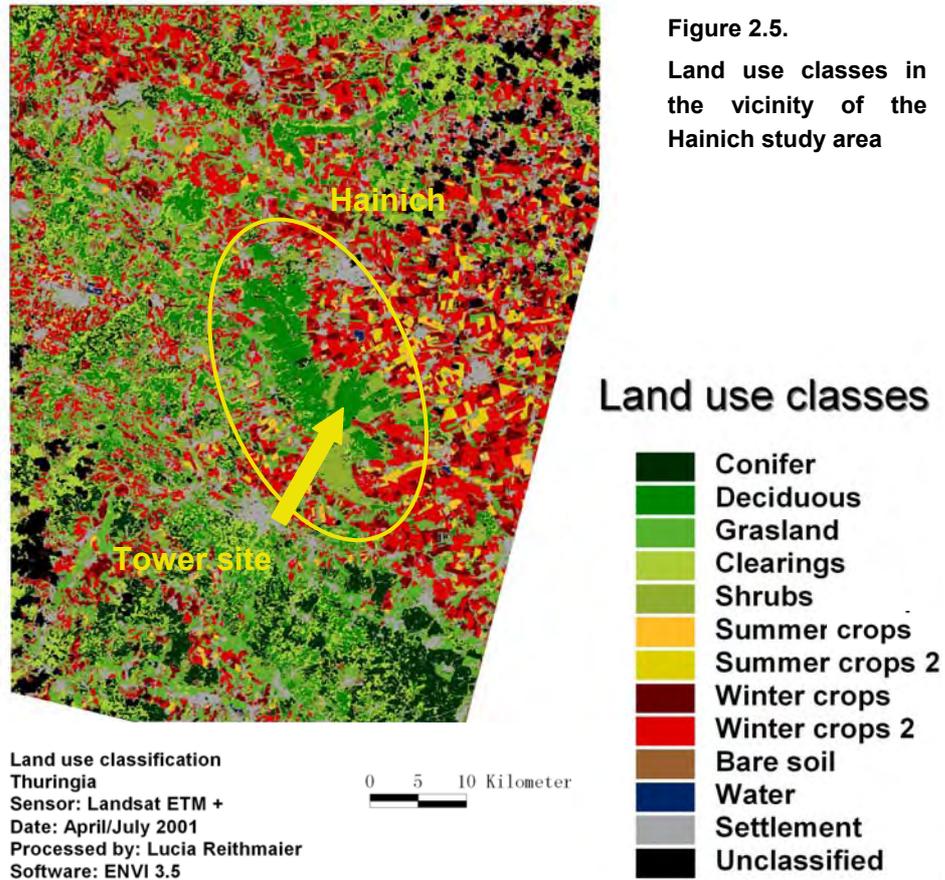

The high spatial resolution of ETM+ images enables to distinguish most of the surface characteristics, e.g. agricultural or urban use. By the comparison of the back scattering spectra for several pictures vegetation type can be derived. An advantage over topographic maps or land use databases like 'Corine' is the actuality.

A differentiation between the most common crops could be obtained by comparing two scenes from April and July (for the characteristics see table 2.7.).

**Table 2.7. Individual crops and their differential characteristics**

	Vegetation Type	Characteristic behaviour	
		Spring	Summer
<b>Summer crops</b>	summer wheat, barley	bare soil	development peak
<b>Summer crops 2</b>	sugar beets	shallow growing height bare soil visible throughout the growing period	development peak
<b>Winter crops</b>	winter wheat, rye	development peak	harvested
<b>Winter crops 2</b>	potatoes	shallow growing height bare soil visible throughout the growing period	harvested

When it became obvious that the 'regional character' of trace gas composition is affected seriously by horizontal transport processes an utilisation of satellite remote sensing data became even more interesting. Since the 'regional footprint' is more extended than assumed so far, land use classifications could provide the information for better interpretation and also for model applications. It was hoped to incorporate the land use information for analyses of the grid boxes along the footprint and, if practicable, also for the description of a nested model area in the surroundings of the location of an air sample.

Therefore the land use classes should be combined with their gas and isotopic signatures in a geographical information system (GIS).

**Table 2.8. Summary of the land use percentages within the study area in Thuringia**

Landuse class	Pixels	Percent
Coniferous forest	332837	6.60 %
Deciduous forest	361068	7.16 %
Clearings	519838	10.30 %
Shrubs	555264	11.01 %
Grasland	440448	8.73 %
Summer crops	91493	1.81 %
Summer crops 2	60718	1.20 %
Winter crops	274158	5.43 %
Winter crops 2	879199	17.43 %
Bare soil	212993	4.22 %
Urban areas	665995	13.20 %
Lakes	7605	0.15 %
unclassified	642934	12.75 %
	5044550	99.99 %

## 2.2. System Configurations and Data Analysis

### 2.2.1. Campaign Equipment

#### 2.2.1.1. Flight Sampling Unit

From the analysis of flight data and laboratory experiments it had become obvious that the flask sampling system, used so far by the MPI-BGC, did not comply with the requirements of the intended project goals. The necessary modifications had to be tested further in the laboratory and during field investigations. The most important technological changes permit: a) to flush and sample the flasks under constant pressure, b) to allow a permanent air flow through the tubing and the system up to the flasks in order to avoid contamination by residual air, and c) to regulate the flow rate individually for the flushing and sampling procedure, according to the environmental conditions, like aircraft velocity and surface structure (see table 3.6). A detailed comparison of the old and the new unit can be found in Appendix A2 and on the CD-ROM.

The installations were also determined by the configuration of the individual aircraft. To avoid contamination caused by the aircraft itself (e.g. exhausts, fuel and oil steams) the sampling inlet had to be fixed strictly at the outermost tip of the wing, in spite of the negative effects for aircraft behaviour.

#### *CONFIGURATION OF THE SAMPLING SYSTEM AND SAMPLING EXECUTION*

The sampling unit can be divided into three major components: a) the inlet, with its tubes and the pump, b) the drying device, particle filter, mass flow controller and switch to c) the flask compartment. Bor silicate glass flasks with 1000 ml volume were used, flushed and prefilled with air of known gas composition and mixing ratios at 2 bar pressure (absolute).

From the inlet at the wing tip the air was sucked in by a double-head membrane pump. Passing a coalescence filter, to trap a large part of water vapour, the gas flowed at different throughput during flushing and sampling to the vertically orientated drying column, filled with magnesium perchlorate  $[\text{Mg}(\text{ClO}_4)_2]$ . After the particle filter the air enters the flask section, or leaves the system into the cabin, when no sampling is carried out. For sampling the air flushes the flasks, which are arranged in a line, first for 2 minutes with a flow rate of  $\sim 10 \text{ l min}^{-1}$  and further

2 minutes with  $\sim 3 \text{ l min}^{-1}$ , before the sample is taken after another 2 minutes at the reduced flow rate of  $\sim 3 \text{ l min}^{-1}$ . To secure a constant pressure of 2 bar inside the drying section and the flasks an electronic mass flow controller was installed in front of the drying column and a pressure conditioner was located at the outlet.

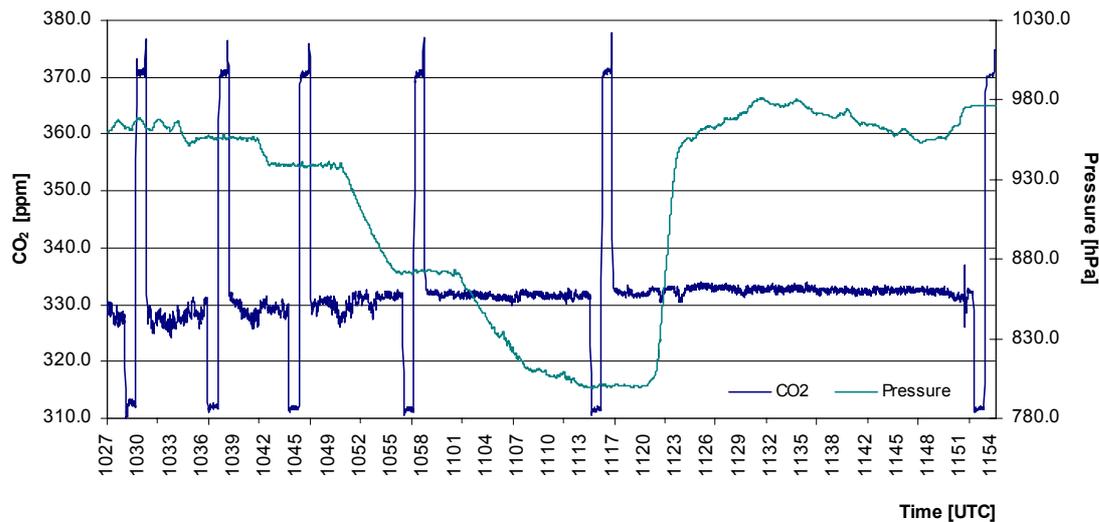

#### 2.2.1.2. Continuous Flight Measurements

It was our intention to obtain information about the CBL structure in general and in particular the local environmental conditions when taking the air samples.

Therefore meteorological parameters, dynamic pressure, geographical latitude and longitude of the aircraft and the  $\text{CO}_2$  mixing ratio were continuously recorded with a frequency of 1Hz [LAUBACH & FRITSCH 2002].

Meteorological parameters measured were air temperature, humidity [Vaisala HMP 233] and air pressure [Vaisala PTB 101B]. The temperature and humidity sensors, capsulated into a radiation shield, were mounted on the front section of the wing, outside the area affected by the slip stream. Close to it the wind / pressure inlet was installed, roughly 50 cm in front of the wing nose. The GPS receiver [d-black Box, DGPS] was fixed on the cabin ceiling and the gas inlet for the continuous  $\text{CO}_2$  measurements was placed close to the sampling unit.

For the continuous measurement of the  $\text{CO}_2$  mixing a Licor 6251 gas analyser was used. Since the system is very sensitivity to pressure and temperature variations, regular in flight calibrations were carried out at each flight level where flask samples were taken (see for example figure 2.6). Therefore two standard gases of known mixing ratio, one with a ratio at the lower and upper end of the expected atmospheric value, were measured at existing pressure instead of the ambient air for one minute each. From the comparison of the measured ambient air and the 'calibration gas' with known mixing ratios the pressure dependency of the Licor instrument can be estimated and corrected.

**Figure 2.6.** Records of CO<sub>2</sub> mixing ratio (raw data, not corrected for temperature and pressure effects) and ambient air pressure from the SPA<sup>13</sup>CE midday flight on 14 August 2002. The spikes in the mixing ratio curve are indicating the calibration events, the steps in the air pressure graph are related to the individual sampling levels. At the lowest sampling height (10:27 – 10:34 UTC) the flight track is following the canopy top, clearly reflected by the oscillating curve. For processed data see for example figure 4.28.

### 2.2.1.3. Ground Reference System

To gain additional information concerning the surface conditions a mobile ground reference system was developed. A small sized and light weight mast was constructed, for operations in particular at remote sites. Therefore an autonomous power supply by rechargeable batteries and solar panels was necessary. The installation and operation of the system should be possible by a single person.

The mast was equipped with instrumentation for near surface profile measurements of meteorological parameters and for air sampling at different levels. Additional data were taken in the upper soil layers. Air temperature and humidity were measured continuously at 0.5, 2.0 and 5.0 m above ground (active ventilated KPK 1/5-Me, Galltec Mela), wind direction (potentiometric wind vane W200P, Vector Instruments) and velocity (potentiometric cup anemometer A100R, Vector Instruments) at 6m, photosynthetic active radiation (PAR), net radiation (LXG055, Dr. Bruno Lange), soil temperature in 5, 10 and 20 cm depth as well as the temperature within the litter layer and 10 cm above ground (107-Temperature Probe, Campbell Scientific), and finally heat flux into and from the soil (heat flux

plates Rinco HFP-CN3, McVan Instruments). During the campaign in Sweden the CO<sub>2</sub> mixing ratio was continuously measured in 2.0 m height by a Licor 6262, for the other field studies a simpler CO<sub>2</sub> sensor was used (GMT222, 0–3000 ppm, Vaisala), because the Licor was no longer available. Sporadically CO<sub>2</sub> soil respiration measurements were carried out (GMT222, 0-2000 ppm, Vaisala). Depending on the intervals for the routine operations the measurement frequency could be fixed between 1Hz up to averages of about 30 sec. The data were recorded by a Campbell CR23X data logger.

For the ground reference flask sampling the system was adapted to the configuration of the flight sampling unit. Sucked in by two pumps, arranged in line, the air was pressed via a drying tube, filled with magnesium perchlorate [Mg(ClO<sub>4</sub>)<sub>2</sub>], through the flask compartment. As for the flight sampling similar preconditioned bor silicate 1000 ml flasks were used. The flow rate was held constant during the 10 minutes for flushing and sampling at 5 l min<sup>-1</sup>. The pressure was regulated by a restriction valve at 1bar relative. Five inlets were placed at 0.1, 0.5, 1.0, 2.0 and 5.0 m above the ground.

A detailed list of the sampling system components is given in the appendix A2 and on the CD-ROM.

## **2.2.2. Equipment for Gas Analyses**

The analysis of trace gas mixing ratios and the isotope ratios were carried out by the 'isolab' gas department of the MPI-BGC [BRAND 1996, JORDAN & BRAND 2001, WERNER et al. 2001, WERNER & BRAND 2001].

Besides air samples from the field campaigns also samples from the system configuration experiments, and finally the calibration gases were analysed.

### 2.2.2.1. Trace Gas Mixing Ratios from Flask Sampling

Gas mixing ratios were derived using a modified *Hewlett Packard 6890* gas chromatograph. For individual trace gases different system configurations and detectors are used: Flame Ionization Detector (FID) for CO<sub>2</sub> and CH<sub>4</sub>, Electron Capture Detector (ECD) for N<sub>2</sub>O. In a second loop the samples are analysed for

the mixing ratios of CO and H<sub>2</sub> using a Reduction Gas Analyzer (RGA), SF<sub>6</sub> is analyzed by another ECD.

All sample and reference gas analyses are performed alternating with a working standard gas. A daily quality control analysis is routinely executed against three standard gases. Calibration routines are carried out at different time intervals. For a scale setup monthly to bi-monthly analyses of calibration standard gases are scheduled, measurements are compared with CSIRO (Commonwealth Scientific and Industrial Research Organisation / Australia), Institut für Umweltphysik, Heidelberg (bi-weekly 4 flasks) and bi-monthly 6 flasks with TACOS (Terrestrial and Atmospheric Carbon Observing System; Laboratory Network of the Carbo Europe cluster).

Special corrections of the analysed results are accomplished with respect to the system offset (reference and working standard, intercomparison) as due to storage time shift, mainly caused by surface processes. The reached analysis precision for the trace gas mixing ratios is listed in table 2.9.

**Table 2.9. Precision of the gas mixing ratio analyses**

<b>Gas species</b>	<b>Unit</b>	<b>Precision</b>
CO <sub>2</sub>	ppm	0.08
CO	ppb	1.0
CH <sub>4</sub>	ppb	1.3
N <sub>2</sub> O	ppb	0.15
H <sub>2</sub>	ppb	5.0
SF <sub>6</sub>	ppt	0.08

A detailed list with the instrument configuration, the analytical procedure as also the calibration specifications can be found in Appendix A3.

#### 2.2.2.2. Isotope Ratios

For the determination of the isotopic ratios  $^{13/12}\text{C}$  and  $^{18/16}\text{O}$  in  $\text{CO}_2$  an advanced Isotope Ratio Mass Spectrometer (IRMS) *Finnigan MAT 252 IRMS* was used. With an additional  $\text{CO}_2$  pre separation (*BGC-Air-Trap*), a precision of 0.012 ‰ for  $^{13}\text{C}$  and 0.02 ‰ for  $^{18}\text{O}$ , respectively, is reached.

To keep high accuracy, calibration routines are executed with a working standard gas twice at the beginning and twice at the end of the analyses; an additional reference standard is included within the flask sample loop. Further on measurements are performed from the ‘comparison CSIRO standard air tanks’.

The data are corrected with respect to the system offset and the shift because of storage time. Additional corrections due to cross contaminations in the dual inlet system, effects depending on mass overlap [ $\text{N}_2\text{O}$  isobaric to  $\text{CO}_2$  (molecular mass = 44, mixing ratio taken from the GC measurements) and the  $^{17}\text{O}$  contribution to mass = 45 ( $^{12}\text{C}^{17}\text{O}^{16}\text{O} / ^{13}\text{C}^{16}\text{O}^{16}\text{O}$ )] were accomplished.

A systematic scheme of the instrumentation and operation is presented in Appendix A3, together with the calibration parameters.

### **3. TEST FLIGHTS AND LABORATORY EXPERIMENTS**

#### **DEVELOPMENT OF AN IMPROVED SAMPLING SYSTEM**

The studies are divided with respect to their intentions into two sections: 1) the test flights carried out before the RECAB campaigns, and 2) the laboratory experiments aiming at the identification of technical problems regarding the modification of the flight sampling system.

Since the test flights provided basic information for the further investigations a brief discussion of the observations and their relevance is given already in this part. A summary of the realized modifications and an assessment of the improvements are given at the end of this chapter.

#### **3.1. Test Flight Measurements**

**October 2000–May 2001**

Before the first complete RECAB field campaign took place (Spain, June 2001) several test flights have been carried out with respect to training of personnel and system testing during fall, winter and spring 2000/2001. Flights were performed above two different sites in Central Germany (Hainich and Gebesee), where the MPI-BGC is operating towers for eddy covariance and meteorological measurements.

##### **3.1.1. Description of the German Study Region**

###### 3.1.1.1. Geography and Climate

###### *GEOGRAPHY*

The study area, located nearly in the center of Germany, is part of the geographical landscape unit of the 'Thüringer Becken' (Thuringian Basin), that is part of the geomorphological major zone of the 'Deutsche Mittelgebirgsschwelle'. The southern border is marked by the mountain ridge of the Thüringer Wald (Großer Finsterberg, 944 m a. MSL), the western rim is formed by the ranges of the Hainich (Alter Berg, 494 m a. MSL) and the Dün, and by the Werra valley. To the north the Harz (Brocken, 1142 m a. MSL) and to the east the Saale River are

defining this entity. The small river 'Unstrut' drains the region along a west-east direction, tributing to the Elbe.

Agricultural land use dominates the inside part of the basin, characterised by a slight rolling morphology, only the west-east striking ridges of the 'Fahnersche Höhe' and the 'Ettersberg' are covered by forests. Common field sizes are up to more than 1 km<sup>2</sup>, dominant crops are wheat, barley, rape, beets and maize. West of the Werra River a more scattered region follows, where also the rate of forested areas, especially on hill tops, become larger.

Along an old trade road the major cities Eisenach (44.000 inhabitants), Gotha (49.000) and Erfurt (197.000) are located south of the flight paths within a west-east distance of 50 km. The towns of Mühlhausen (38.000) and Bad Langensalza (22.000) were enclosed by the flight pattern of the flux aircraft, many small villages are unequally distributed within the whole study area (see figure 3.1 on next page).

#### *CLIMATE*

With respect to the topography the study region can be divided into subatlantic and submountain climate zones. South-westerly winds prevail. Yearly mean temperature for Mühlhausen (300 m a. MSL) and Erfurt (316 m a. MSL) is 8.7°C, the yearly mean sum of precipitation is 736 mm, respectively 581 mm (averaging period 1961 – 1990).

#### 3.1.1.2. Field Sites

##### *HAINICH TOWER*

Within the Hainich National Park, a small mountain range north of Eisenach, the Max-Planck-Institute for Biogeochemistry operates a field site at a 43.5 m micrometeorological / flux tower, operational since 1999. The Hainich, a limestone ridge, stretches over a distance of 20 km in north-west / south-east direction, the extension from west to east is about 7 km. At the western side a steep slope leading to the Werra valley, whereas the decline to the eastern basin is not as steep and more gently. The typical form of silviculture is selective cutting ('Plenterwaldwirtschaft'), where only single trees are harvested and replaced by natural young growth. As large parts of the area were intensively used from the mid of the 1930s for military training the forest looks rather primeval. Beech, ash

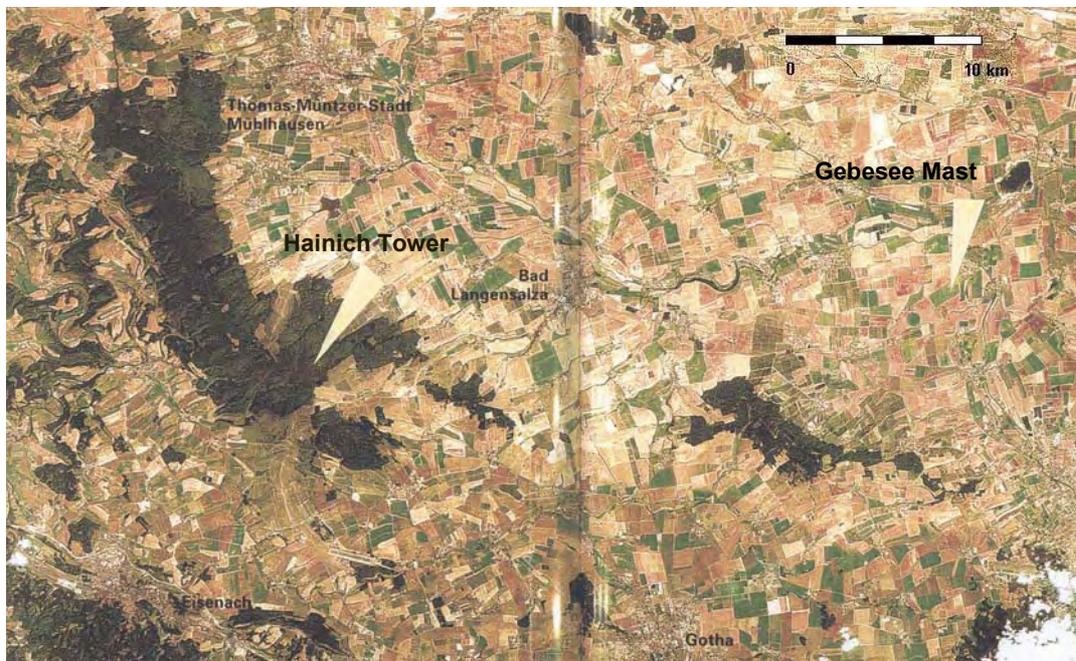

and oak are the predominant tree species, with all age classes up to 250 years. The mean tree height around the tower site is ~ 33 m, the height of the herbal understory ~ 0,3 m.

Hainich Tower; 51°04,7'N / 10°27,1'E, 439 m above MSL

#### *GEBESEE MAST*

Since January 2001 a 6 m micrometeorological mast is operational within a intensively used agricultural area 2 km southwest of Gebesee. Predominant in the direct surroundings of the site are wheat, barley, rape and maize. To the south also some small patches were planted with peppermint and sunflowers. During the REcab summer campaign in July 2001 the harvest of the cultivated crops started. Wheat, barley and rape were harvested successively during the flight days, which become also obvious from the aerial photograph presented in the documentation folder.

Gebesee Mast; 51°06,1'N / 10°55,0'E, 162 m a. MSL

**Figure 3.1.** Satellite image of the German study area (picture from WINTER et al. 1998, modified)

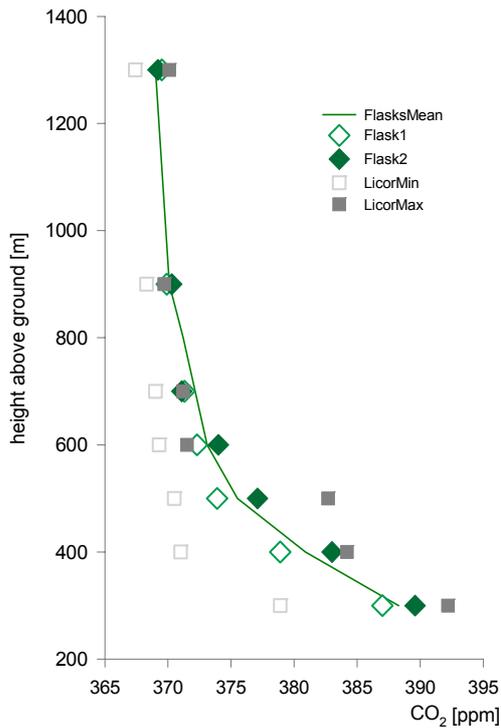

### 3.1.2. Hainich Flights      October 2000

First flight samplings were performed following the sampling strategy and using a similar flask sampling system as described by LAUBACH & FITSCH [2002] and by LLOYD et al. [2002] above the Hainich between 20 to 23 October 2000. Surprisingly the results were completely contrary to what was expected: in between paired flasks CO<sub>2</sub> mixing ratio differences of up to 4 ppm occurred (displayed in figure 3.2). And as shown in figure 3.3, on 23 October the data from the morning and the afternoon sampling did not decrease over time but increase.

Since the 'isolab' aimed to use the paired flasks also as an internal quality control, the first tests were focussing on the differences between twin flask samples. In almost all cases the CO<sub>2</sub> mixing ratio of the second flask was higher than the first. Two reasons seemed to be responsible:      1) the problem is generated by the system configuration. Perhaps caused by an insufficient flow rate, so that remnants of the calibration gas were left in the flasks. Or cabin air entered through a leakage or a dead end.      2) The ambient air might be less well mixed than expected. Therefore a highly variable mixing ratios occur on small spatial scales. A corollary would be that the flask pairs can not be used as a quality criterion for the laboratory.

In a first step the sampling unit was checked for leakages with a negative result, but, regarding a contribution from 'dead end residual air', the outlet was identified as a potential error source. However, in laboratory experiments it was not possible to attribute the high mixing ratios in the second flask solely to the system configuration.

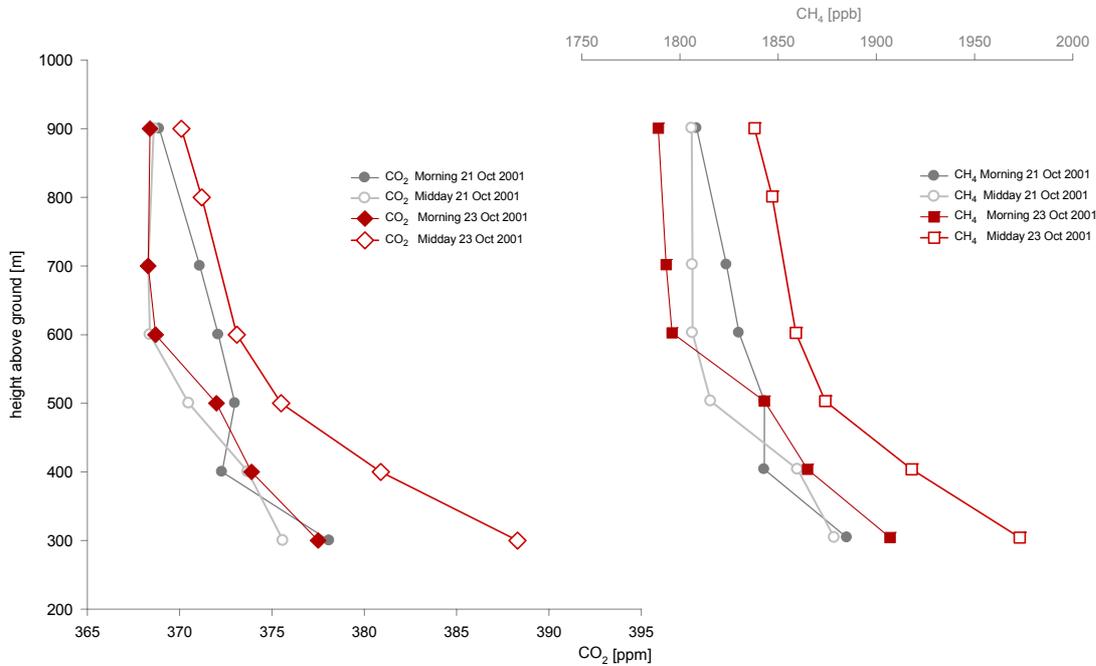

The second attempt focused on the distribution of the CO<sub>2</sub> mixing ratios at each individual sampling level. If small scale variability exists, this should be noticeable as well in the continuous records. Therefore the calibrated Licor measurements were analysed with regard to mixing ratio variability for the time frames, when the flask sampling procedures were performed (see figure 3.2). Thereby variability up to 13 ppm was identified at the lowest levels; the absolute variation levelled off with increasing sampling height. Hence high variability of the gas mixing ratios on small spatial scales has to be assumed, even above relative uniform vegetation.

**Figure 3.2.** CO<sub>2</sub> mixing ratio variability obtained from a vertical profile flask sampling flight on 23 October 2000 (*Hainich / Germany*)

Flask sampling vs. the Licor online minima and maxima values, recorded during the period the flask sampling procedures were performed

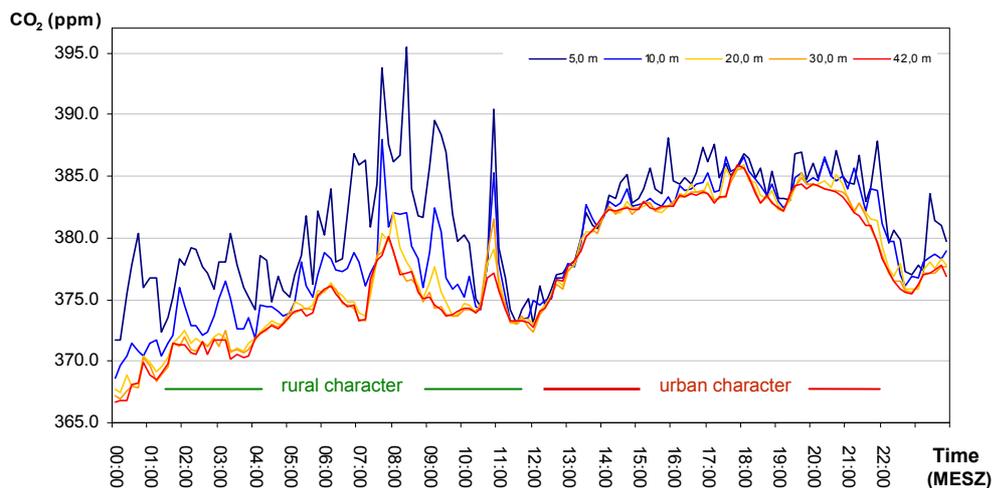

Also the sudden increase of the CO<sub>2</sub> mixing ratio during day time, as observed on 23 October, was unexpected. Even if the photosynthetic CO<sub>2</sub> uptake was reduced because of the beginning senescence, the results from the days before reflected an activity high enough to decrease the atmospheric CO<sub>2</sub> by a recognizable amount.

**Figure 3.3.** CO<sub>2</sub> and CH<sub>4</sub> mixing ratios from flasks sampled during morning and midday flights on 21 and 23 October 2000 (*Hainich / Germany*)

Since the highest values were observed near the ground comparisons were performed with the meteorological records and the CO<sub>2</sub> profile data of the Hainich tower (see figure 3.4.).

As expected, the CO<sub>2</sub> mixing ratio increased with the night time respiration until the photosynthesis became more active around 8:00 AM. In the following the mixing ratio decreased, despite several CO<sub>2</sub> peaks a minimum of 373 ppm was observed at noon, when a rapid increase occurred, leading to values much higher than during night time. These observations can be explained by the analysis of the wind data. During day time a change from westerly to more southerly directions was recorded. Thereby the study site was affected in the afternoon by air of urban origin from the surroundings of Eisenach. During the previous night and the early morning hours of the day air of more rural character passed the Hainich.

**Figure 3.4.** CO<sub>2</sub> profile data recorded at the *Hainich* Tower on 23 October 2000

Thus it has to be noticed, that changes of the main wind direction and air mass changes may prevent the CBL budgeting.

### 3.1.3. Winter Flights January and February 2001

To monitor the seasonal characteristics, the next series of flights were performed during January above the 'Hainich', and in February above the agricultural site 'Gebesee'.

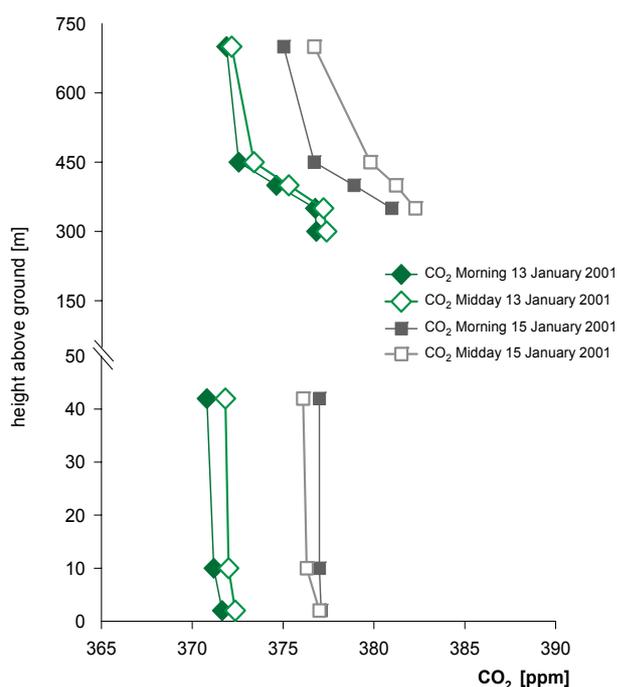

Compared with the data from October the winter time samples contained higher CO<sub>2</sub> mixing ratios with an elevated amount of <sup>12</sup>C, but lower mixing ratios of N<sub>2</sub>O and CH<sub>4</sub>, which are both related to soil processes. The averaged data from the flights in autumn and winter, respectively, are listed in table 3.1.

**Table 3.1.** Average CO<sub>2</sub> and N<sub>2</sub>O mixing ratios and delta<sup>13</sup>C values for October and January sampling flights above the 'Hainich'

	October	January
CO <sub>2</sub> [ppm]	377.5	384.3
N <sub>2</sub> O [ppb]	319.0	318.5
δ <sup>13</sup> C [‰]	-8.147	-8.826

Similar to the autumn experiment small scale variability and a decrease of the CO<sub>2</sub> mixing ratio with height for the entire flight profile were observed. Also strong day-to-day variation was monitored. However the tower measurements showed a deviation of approximately -10 ppm. 3 to 4 ppm of the discrepancy might be attributed to uncontrolled calibration gases used for the tower instrumentation.

On 15 January 2001 the CO<sub>2</sub> mixing ratio decreased during the day at the tower, whereas the flight flask samples showed an increase. Thus the tower data could not be consulted as direct ground references.

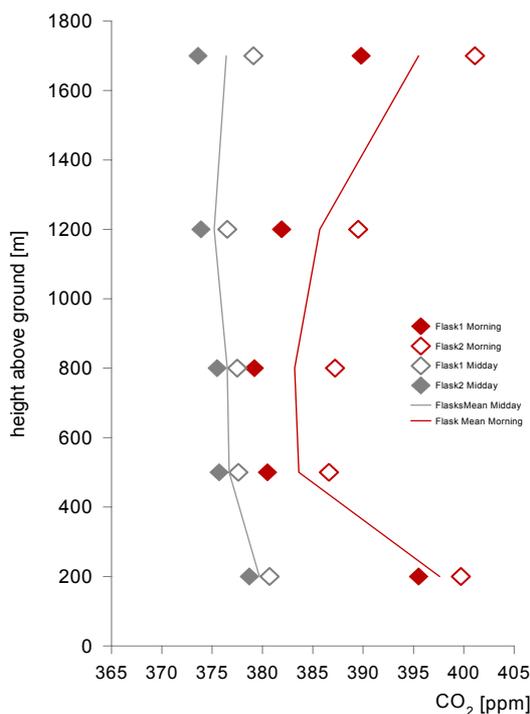

**Figure 3.5.**

CO<sub>2</sub> mixing ratios measured at the *Hainich* Tower and obtained from flight samples above the Hainich on the 13 and 15 January 2001.

### 3.1.4. Gebesee Flights May 2001

Flights were performed above the agricultural site at Gebesee three times per day from 9 to 11 May 2001 (see figure 3.6). One additional flight for specific tests of the pump system was performed on 26 May. Caused by flight restrictions the lowest level was 150 m above ground.

**Figure 3.6.** CO<sub>2</sub> mixing ratios from flasks sampled on 10 May 2001 above the agricultural measurement site Gebesee (shown are the results from the morning and from the midday flight). Notice the increasing flask pair differences with height.

Remarkable are the strong decrease of the CO<sub>2</sub> mixing ratio within the course of the day, the flask pair difference increasing with height and that the much higher mixing ratios of the second flask from the morning flight could not be recognized anymore in the midday data.

Even if the results can be explained as being due to assimilation by vegetation the functionality of the modified sampling unit was unsatisfactory. At the lower levels the pump configuration met the requirements. But the flow rate became insufficient with increasing height, caused by the loss of efficiency at reduced ambient air pressure. The decreasing flow rate caused an insufficient flushing of the flasks. Further tests and calculations were carried out (see chapter 3.2.1) to define the requirements for the improvements of the inlet and of the pump section.

Because of the difficulties caused by the insufficient flushing an interpretation of the observed flask pair differences is not appropriate here.

### 3.2. Development of a modified Flask Sampling System

Since it had become obvious from the test flights that there are big discrepancies between mixing ratios of paired flasks laboratory experiments were carried out to identify disturbances provoked by the original sampling system, and to verify the modifications of the new flight sampling unit.

#### 3.2.1. Conventional Flight Sampling System: Test of the inlet tubing and of the gas exchange rate October 2000 – May 2001

The original system was configured with different materials, in particular plastics, which might be unsuited due to adsorption at surfaces or permeability. Especially the inlet tubes seemed to be highly sensitive, because of its length of more than 7 meter.

For the laboratory experiment the common sampling flasks and conditioner gas were used. The air samples were analyzed for the mixing ratios of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O as well as for delta<sup>13</sup>C and delta<sup>18</sup>O. Two samples were taken, one direct from the gas tank (for reference) and one after passing the tube.

**Table 3.2. Isotopic ratios of the calibration gas filled into sample flasks either directly from the air tank or via the plastic tube used for the flight sampling**

Flask	conditioner gas direct		Flask	conditioner gas via plastic pipe

<b>Std.Dev.</b>	<b>± 0.016</b>	<b>± 0.028</b>	<b>Std.Dev.</b>	<b>± 0.016</b>	<b>± 0.013</b>

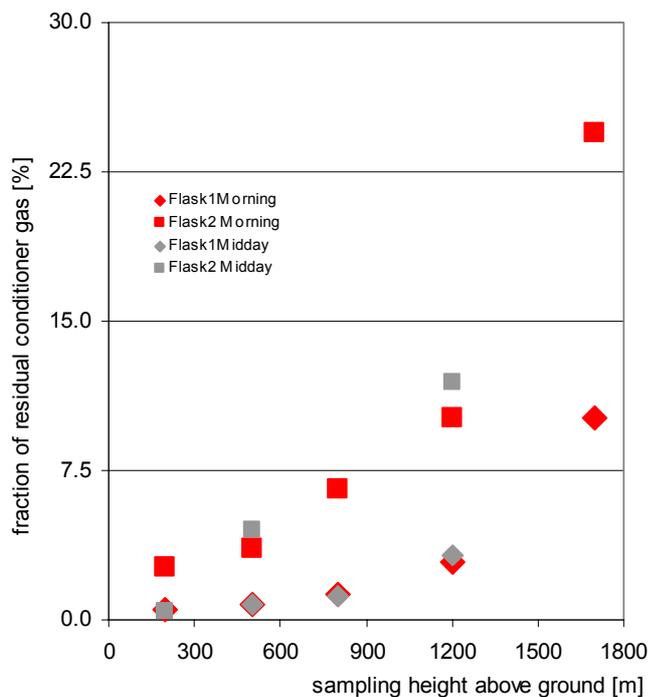

Mean direct *and* via plastic pipe: del<sup>13</sup>C [‰] = -8.509 del<sup>18</sup>O [‰] = -2.170

From the results of the trace gas analysis and the isotope ratios (see Table 3.2.) a differentiation caused by material related interferences could not significantly be excluded. In consequence the complete PVC pipes were replaced by decabon<sup>®</sup> tubes.

Because residual humidity was detected in the samples from the former flights the horizontal drying tube was removed and a vertically orientated column installed.

To enable a constant operation under final pressure conditions an experimental system with two pumps of higher capacity was constructed and tested in the laboratory. During the flight series in May 2001 the modified set up was verified under real operational conditions (see 3.1.4). It became obvious that the capacity of the two pumps was still not high enough to enable the required flow rates at larger heights.

In order to further study the observed large flask pair differences in the CO<sub>2</sub> mixing ratio (see figure 3.7) a laboratory experiment was carried out to qualify the exchange rate for both flasks under flushing and filling conditions. It could be shown that the removal of the conditioner gas is in fact more efficient from the first flask than for the second. When combining the information on exchange rates, mixing ratios of the conditioner gas and the flow rates noticed during the flights a rough estimate of the residual conditioner gas in the sampled flasks is obtainable.

**Figure 3.7.**

Fraction of residual conditioner gas inside the flasks after flushing 4 minutes and sampling 2 minutes. Morning and midday flight on 10 May 2001 above the agricultural site Gebesee. Uppermost level sampled only during the morning flight.

### **3.2.2. Conclusions of the first laboratory experiments and test flights**

The most important findings of the test flights and the laboratory experiments are:

- Flask pair differences, as frequently found are reflecting at least  
1) the occurrence of high mixing ratio variability on small spatial scales  
and 2) effects of insufficient flow rates.
- Mixing ratio changes between lights of one day, are to large extend due  
to air mass changes
- The differences of flight samples to those from the ground are related to  
1) different footprint sizes, 2) failures of the calibration standards and 3)  
errors made during individual measurements and originating from  
deficiencies of the sampling system.

At least two modifications were needed: the flask sampling system had to be improved and, even more crucial, assumptions of the CBL approach were not satisfied under certain weather conditions.

Regarding the sampling and the flight strategy the focus has to be a lower sampling height and a flight pattern for the entire vertical profile under strict GPS guidance.

### 3.3. Modified Flight Sampling System

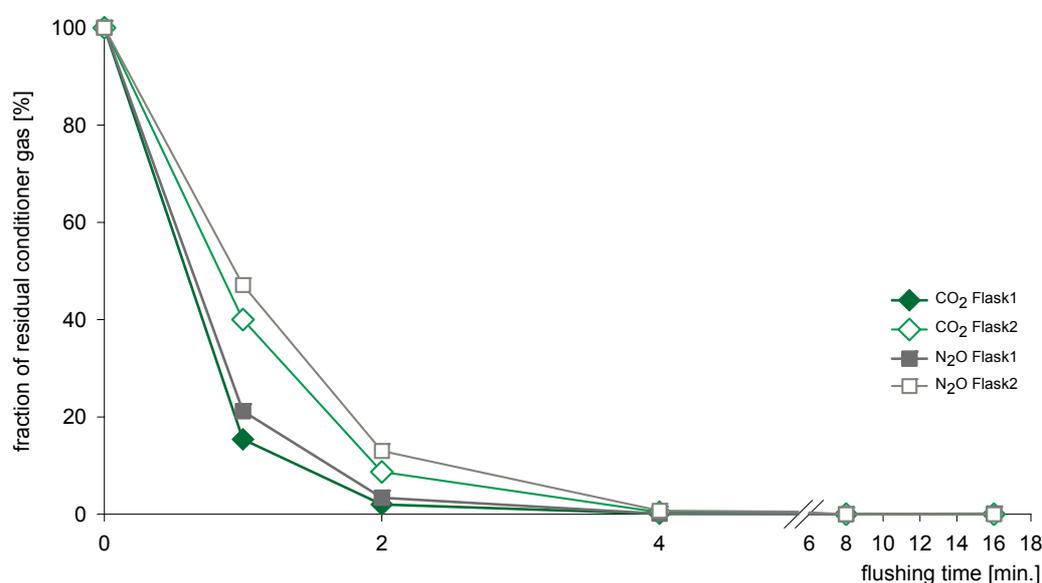

#### 3.3.1. Adjustment of the flow rate and tests regarding effects of the drying reagent on the CO<sub>2</sub> mixing ratio

September - December 2001

Since the Spain summer campaign the new 'Flight Sampling Unit' was operational. Because of still recognizable impairments and to test the modifications further laboratory experiments were carried out. Their goal was an improved flushing and exclusion of potential problems caused by the chemical drying agent.

##### 3.3.1.1. Exchange characteristic

Intention was to determine the exchange rate for two flasks arranged in a line, at typical pressure and flow rate of the modified sampling unit. Therefore six flask pairs, filled with a gas mixture of known composition, were flushed with synthetic air for time intervals of different duration from 0 to 16 minutes. The individual flasks were subsequently analysed by gas chromatography for the mixing ratios of CO<sub>2</sub> and N<sub>2</sub>O, displayed in figure 3.8.

**Figure 3.8.** Laboratory experiment: Fraction of residual conditioner gas inside the flasks as a function of flushing time. Air was analyzed for the mixing ratios of CO<sub>2</sub> and N<sub>2</sub>O

A difference between the first and the second flask became obvious regarding the exchanged fraction of the conditioner gas. The residual CO<sub>2</sub> mixing ratio after one

minute was 15.4 % in Flask1, but 40.0 % in Flask2. After four minutes still small fractions of 0.1 %, respectively 0.4 % were left. Unexpected was the reduced removal rate of N<sub>2</sub>O from both flasks. Responsible for this might be gas specific behaviours, like surface interactions, but until now no studies have been carried out regarding such processes.

### 3.3.1.2. Influence of the drying medium on the carbon dioxide mixing ratio

In particular due to the sensitivity of the oxygen isotope to liquid water it is necessary to dry the sampled air at least to a dew point below 2°C [GEMERY et al. 1996]. The sampling unit is therefore equipped with a stainless steel coalescence filter and a tube filled with the chemical drying agent magnesium perchlorate [Mg(ClO<sub>4</sub>)<sub>2</sub>]. For the flask pair differences in mixing ratios also [Mg(ClO<sub>4</sub>)<sub>2</sub>] might be responsible because of pressure dependent adsorption and desorption.

Focus of the first experiment was to study, whether there is any effect. The examination was done under flight-typical pressure conditions with air of known composition from a tank, but with different time frames for flushing and sampling. Additionally a reference flask pair was flushed and filled with a constant rate of 2 l min<sup>-1</sup> for 20 minutes at reduced initial pressure.

From the results of the analysis, as shown in table 3.3., a pressure dependency could be confirmed: under high pressure conditions, which are associated with the flushing procedure, an adsorption of CO<sub>2</sub> occurs. When reducing the inside pressure, by a lowering of the flow rate, the CO<sub>2</sub> is slowly desorbed again.

Therefore the chemical drying tube was located behind the mass flow controller and the restriction valve was replaced by a 'pre-pressure-controller'. Though this compartment was configured to provide stable pressure conditions.

**Table 3.3. Comparison of gas mixing ratios of CH<sub>4</sub>, CO<sub>2</sub> and N<sub>2</sub>O before and after passing a drying tube filled with magnesium perchlorate.**

Flow rates: for flushing 10 l / min.; for filling 2 l / min.

The improvements were tested by placing the drying tube either in front of the mass flow controller, or within the pressure stabilized compartment. In addition reference flasks were sampled directly behind the gas tank. The first configuration resulted in a reduced CO<sub>2</sub> mixing ratio, but the results from the pressure-stabilized system showed values in the range or even slightly higher as obtained from the reference measurements.

### 3.3.2. Comparison of the different sampling systems

January 2002

Due to the influence of the drying reagent on the CO<sub>2</sub> mixing ratio an additional laboratory experiment was conducted, in order to investigate the individual behaviours of the different sampling units. The results are listed in table 3.4.

In a large storage room the basic and the modified flight sampling system, the ground sampling unit and a reference set up without drying compartment were operated concurrently. The first test sampling was performed with all systems simultaneously. In a second test the sampling was carried out solely with the new flight system, but with modified flushing and sampling periods. Finally in a third test combined sampling was executed again. The aim was to compare the results from the basic flight system and the modified flight unit, which was operated without the drying section. For the detailed system configurations and the experiment protocol see Appendix A5.

Although the experiment was performed inside a wide-sized, non public room to avoid disturbances by air mass exchanges, an increase of the CO<sub>2</sub> mixing ratio during the sampling period occurred. This increase has to be taken into account when interpreting the data, because the sampling durations were different for the individual systems (for instance 10 minutes 'Ground reference unit' and 2 minutes 'Flight sampling system'). The same trend is also recognizable for the individual flask pairs, where, except one case, the first flask contains higher CO<sub>2</sub> mixing ratios than the second flask. These records are contrary to the former observations from the real flight samplings, where in most cases higher values were measured in the second flask.

The high differences for CH<sub>4</sub> and CO<sub>2</sub> obtained from the reference and from the flight system with the modified flushing rate might be caused by an insufficient flushing procedure. Even if the flow rate was determined to be high enough to exchange the air inside the flasks at least four times, the second flask contained still residuals of the conditioner gas.

By the comparison of the flight system with and without the drying section no significant differences could be found. The range of the discrepancies, which were recorded also for the ground sampling unit and, in particular for the basic flight system, are clearly below the amount of change that was monitored throughout the

period of the complete experiment. Also the increase of the mixing ratio, observed in the first flasks, might be related to this general shift. Also the discrepancy between the flasks sampled with the old system in the third test might be interpreted as an indication for spatial CO<sub>2</sub> variability even inside a closed room without distinct CO<sub>2</sub> sources.

**Table 3.4. Results of the experiment comparing the diverse sampling units**  
(indicated in red are outliers excluded from the analysis)

Std.Dev.			1.8	1.4	0.0

The difference in the N<sub>2</sub>O mixing ratios observed between the sampling systems seems not to be caused by the configurations. As a general decrease of the N<sub>2</sub>O mixing ratio can be recognized during the test period it is most likely that this might be also the main cause for the variability between the systems (see for reference the test documentation with the time schedule in Appendix A5).

For the modified flight sampling unit no significant influence of the [Mg(ClO<sub>4</sub>)<sub>2</sub>] on the CO<sub>2</sub> mixing ratio could be recognized any more. However, an effect on the mixing ratio of H<sub>2</sub> could be identified from the data obtained by the later field campaigns when H<sub>2</sub> was implemented regularly in the analytical scheme. This has to be taken into account for the interpretation of the results.

### **3.4. Summary of the modifications and assessment of the improvements**

Modifications of the system have been carried out also during the first RECAB flight campaigns until November 2001, when with the Valencia winter experiment the finally configured system could be used. For an overview of the development and the use of the individual system configurations see table 3.5. References to laboratory experiments and further modifications and tests during the campaigns are given in chapter 4. 'RECAB field experiments' and chapter 5. 'Discussion'.

#### **Assessment of the improvements**

The modifications resulted in significant improvements with respect to the data collection. In particular the unification of the sampling process by the continuously operation under final pressure condition at all levels throughout the entire profile and the implementation of the documentation, which was not possible with the former flight sampling system used by the MPI-BGC, established direct comparability of individual samplings. An overview of the realized improvements is given in table 3.6.

Even if the problems with the chemical drying agent could be solved with respect to the CO<sub>2</sub> mixing ratio, a systematic impairment seems to continue for hydrogen. Since H<sub>2</sub> was used only as an additional tracer for anthropogenic contaminations, the importance for the carbon investigation is limited, when keeping these problems for data interpretation in mind. Nevertheless it has to be pointed out, that there are still some smaller problems which have to be removed in further examinations.

**Table 3.6. Improvements realized by the new 'Flight Sampling Unit'**

<b>Parameter</b>	<b>Modification</b>	<b>Result</b>

A detailed comparison of the system configuration and the operation scheme of the initial and the modified sampling units is given in Appendix A2 and on the CD-ROM.

## 4. RECAB FIELD EXPERIMENTS

**JUNE 2001 – AUGUST 2002**

The field campaigns served two interests: Firstly, data acquisition with respect to the regional carbon budgets, the prior aim of the RECAB project. Secondly, performance of specific experiments to test and evaluate technical modifications and subsequent adaptation of the investigation strategy.

To achieve both goals this chapter is divided into two sections. The first part will focus on the intentions and the observations of the field campaigns in chronological order. Following on these will be regionally interpreted, by examining specific aspects.

**Table 4.1. Schedule of the RECAB field campaigns and nomenclature of the sampling locations**

Region	Period	Flight Profile Sites	Ground Reference Sites	Flight Days
Valencia (Spain)	06/2001	Rice, Orchard, Mare	Rice, Orchard	6
Thuringia (Germany)	07/2001	Hainich, Gebesee	Hainich	5
Upland (Sweden)	08/2001	Norunda, Florarna	Florarna (Swamp, Forest)	7
Valencia (Spain)	12/2001	Rice, Orchard, Macchia, (Mare)	Rice, Orchard, Macchia, Highway	6
The Netherlands	01/2002	Forest, Maize, Cabauw	Loobos, Maize, Marshland	5
Lazio (Italy)	06/2002	Tuscania, Orvinio	Roccarespampani, Orvinio (Meadow, Valley)	2.5
The Netherlands	07/2002	Forest, Maize, Cabauw	Maize, Marshland	3
SPA <sup>13</sup> CE (Hainich, Germany)	08/2002	Hainich, (Holzland)	Hainich	3.5

The complete data sets, the descriptions of the studied areas and notes about the flight operations, as well as a picture collection for each region, respectively campaign, can be found in the documentation folders on the CD-ROM.

## 4.1. Data Acquisition and Observations

### 4.1.1. Valencia Summer Experiment

17 June – 7 July 2001

First experiment with the modified flight sampling system

The first field campaign using the modified flight sampling system took place in a coastal zone with intensive agriculture south of Valencia (Spain).

The main foci of the investigation were CO<sub>2</sub> mixing ratio variations and the identification of contributions by individual sources and sinks. Further, additional air samples were taken for the first time at ground level in an apricot orchard during night and day, as well as in the rice field area around noon.

Profile flights were carried out above an area dominated by orchards of citrus and apricot plants and above a plain with wetland rice cultivation. An overview of the observed trace gas mixing ratios and the delta <sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.2.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
<b>Lowest Level</b>	360 - 380		1802 - 1919	318 - 323			-7.746 - -8.638
<b>Free Troposphere</b>	364 - 379		1764 - 1966	316 - 326			-7.940 - -8.335

Heights LL and FT: 100 – 150 m / 1500 – 2000 m

Number of flight days: 6

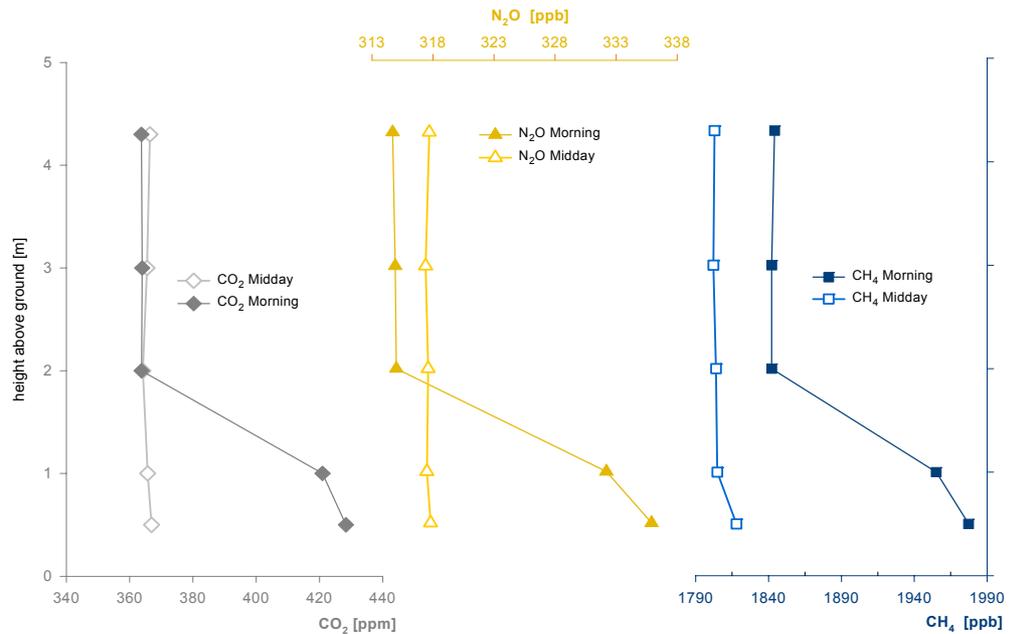

Number of profile sites: 2

**Table 4.2.** Range between the maxima and minima of the mixing ratios and the delta <sup>13</sup>C values obtained from the flask sampling during the summer campaign (17 June to 7 July 2001) in the Valencia region.

Ground level samples were taken at one day around noon within the rice fields and two times, on 3 July before sunrise and on 5 July at noon, inside an apricot orchard. Figure 4.1 presents the data from the orchard samplings.

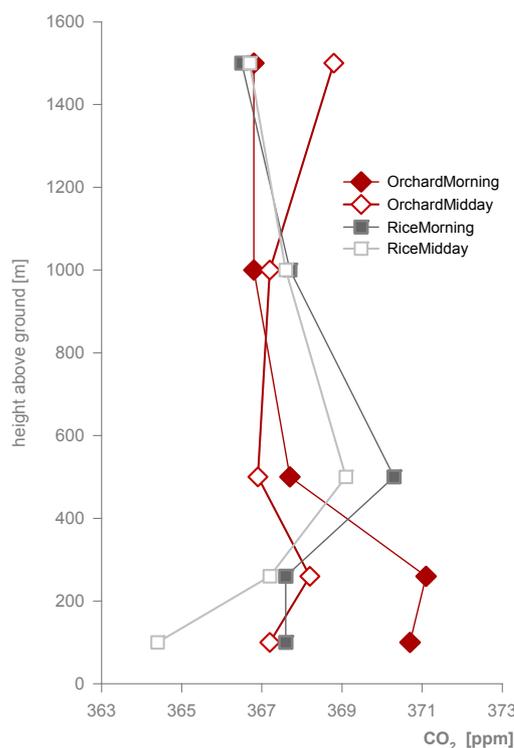

The height of the trees was approximately 3.5 m. During the night of 2 July the plot was flooded for watering; high soil moisture was still recognizable the night after this flooding event. However, when taking the samples on 5 July the top soil was completely dry again.

Obvious are the high values during night time below the canopy top. This steep gradient does not occur during day time. Instead, a rather stable value of the mixing ratio can be observed throughout the entire profile for all gas species. However, a difference can be recognized because of the increasing N<sub>2</sub>O mixing ratio from the morning to midday sampling, which is in contrast to the CH<sub>4</sub> mixing ratio changes.

**Figure 4.1.** Mixing ratios of CO<sub>2</sub>, N<sub>2</sub>O and CH<sub>4</sub> from samples taken inside the apricot Orchard (Valencia / Spain) before sunrise (3 July 2001) and around noon (5 July 2001).

Representing the flight activities, two consecutive days are presented in figure 4.2. At both sites the CO<sub>2</sub> decrease is highest near the ground, whereas the upper profiles differs from each other: the profiles from the rice fields are characterised by an increase of the mixing ratio sampled around the 500 m level, which is stable until the afternoon (not shown). On the other hand a CO<sub>2</sub> increase within the profiles above the orchards can be recognized for the sample levels 1000 and 1500 m between the morning and the midday flight.

**Figure 4.2.** CO<sub>2</sub> mixing ratios from sampling flights performed above the 'Orchard site' (Valencia / Spain) on 3 July 2001 (around 8:00 and 11:00 UTC) and the rice field area on 4 July 2001 (around 9:00 and 12:00 UTC).

#### 4.1.2. Thuringia Summer Experiment

15 July – 2 August 2001

The flight investigation took place around the Hainich and the Gebesee sites in Thuringia / Central Germany (for description of the region see also chapter 3.1.1.). An overview of the observed trace gas mixing ratios and the delta<sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.3.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
Lowest Level	355 - 403		1815 - 1981	316 - 328			-7.736 - -9.720
Free Troposphere	356 - 364		1781 - 1882	314 - 319			-7.710 - -7.850

Heights LL and FT: 90 – 340 m / 1800 – 2500 m      Number of flight days: 5      Number of profile sites: 2

**Table 4.3.** Range between the maxima and minima of the mixing ratios and the delta<sup>13</sup>C values obtained from the flask sampling during the Thuringia summer campaign (15 July to 2 August 2001).

Figure 4.3. presents the CO<sub>2</sub> mixing ratios, obtained from the flights carried out above the agricultural field site 'Gebesee' (23 July; morning flight: 9:00 UTC, afternoon flight: 16:00 UTC) and around the Hainich Tower (24 July 2001; morning flight: 7:30 UTC, afternoon flight 16:00 UTC).

For the 'Gebesee' data the high mixing ratios sampled during the morning flights near the ground and the steep gradient to the samples taken at the higher levels are obvious. Contrary to the 'Gebesee' data lower CO<sub>2</sub> mixing ratios with an only slight difference between morning and afternoon samples were observed at the lower levels above the 'Hainich'. Remarkable is the increasing difference of morning and afternoon samples up to the free troposphere.

**Figure 4.3.**

CO<sub>2</sub> mixing ratios from flights performed above the agricultural site 'Gebesee' and above the 'Hainich' forest (Germany).

Notice the interrupted scale on the x-axis.

### 4.1.3. Uppland Summer Experiment 11 August – 9 September 2001 Implementation of additional trace gas analyses

Extensive agriculture and urban settlements are of only minor importance at the most northern RECAP field site. Boreal forests and wetlands are the major landcover types.

Since it became obvious in previous campaigns that advection is a major factor affecting the budgeting strategy, the need to include more gases into the analysing scheme was anticipated. In addition a reduced height of the lowest flight level was desirable, to find the influences of local sources or sinks.

The flask analysis was therefore carried out for additional trace gases. For most of the samples from 19 August 2001 onwards mixing ratios became available for CO, H<sub>2</sub> and SF<sub>6</sub>.

The emphasis of the investigations was on the diurnal variation of the CO<sub>2</sub> mixing ratio and on the comparison of two different, but characteristic major land units of the study region - the forest site at Norunda and the Florarna wetland area. Further, special attention was paid to the vertical profiles at Florarna, focussing on the contributions of the swampy and the wooded parts on a daily time scale. Ground reference data were obtained by measurements and sampling inside the forest and within the open swamp, using the new mobile mast.

An overview of the observed trace gas mixing ratios and the delta <sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.4.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
<b>Lowest Level</b>	350 - 380	100 - 134	1807 - 1889	316 - 319	415 - 474	4.83 - 5.07	-7.077 - -8.536
<b>Free Troposphere</b>	354 - 364	96 - 122	1783 - 1869	316 - 321	452 - 492	4.78 - 5.01	-7.364 - -7.955

Heights LL and FT: 60 - 90 m / 1980 – 2440 m      Number of flight days: 7      Number of profile sites: 2

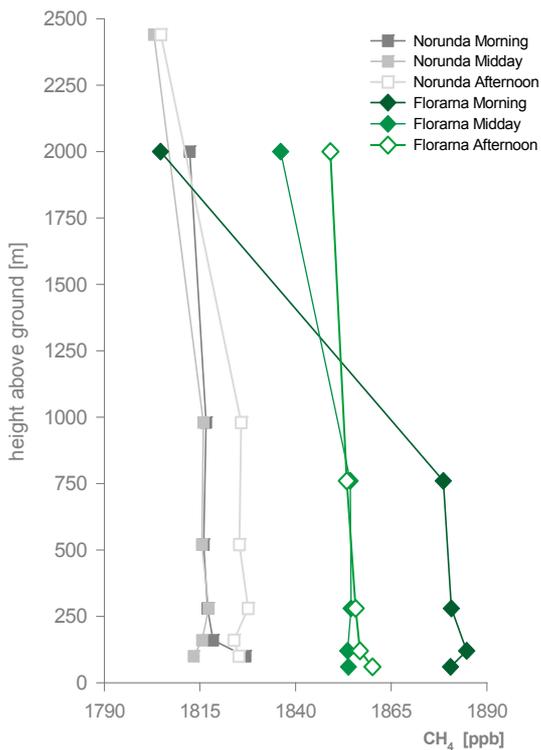

**Table 4.4.** Range between the maxima and minima of the mixing ratios and the delta <sup>13</sup>C values obtained from the flask sampling during the Swedish summer campaign (11 August to 9 September 2001).

As examples for the flight profiles the results from samplings around the Norunda Tower on the 19 August and above the Florarna wetland on the 30 August are presented in figures 4.4. and 4.5. At both locations, however more distinct at the Florarna site, a decrease of the CO<sub>2</sub> mixing ratio can be recognized during the day, while the <sup>13</sup>C isotope ratio is increasing.

Contrary to the development of the CO<sub>2</sub> mixing ratio CO increases during the day at the Florarna site and at the Norunda location. At Norunda a clear jump up between the midday and the afternoon flight was observed, even for the sample level within the free troposphere.

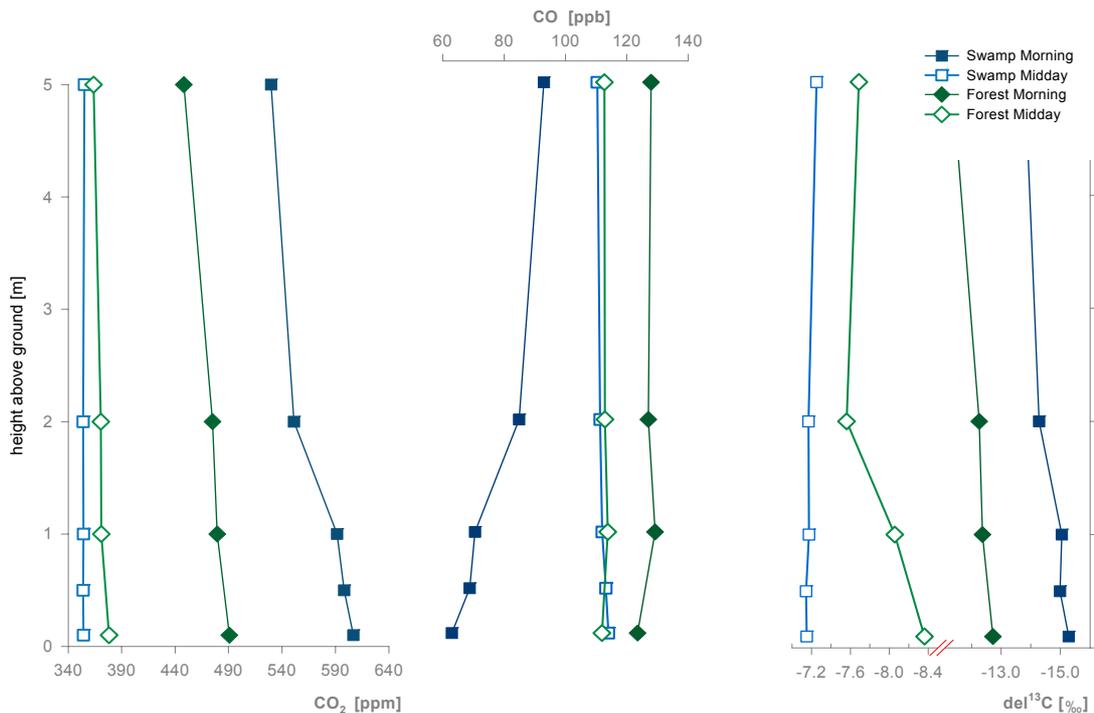

**Figure 4.4.** CO<sub>2</sub> and CO mixing ratios and delta <sup>13</sup>C values from the flight profiles around the *Norunda* Tower on 19 August 2001 and above the *Florarna* nature reserve on 30 August 2001 (Uppland / Sweden).

**Figure 4.5.**

CH<sub>4</sub> mixing ratios from the flight profiles around the *Norunda* Tower on 19 August 2001 and above the *Florarna* nature reserve on 30 August 2001 (Uppland / Sweden).

As seen before from the flight samples also the data from the ground reference samplings (see figure 4.6.) are indicating a CO<sub>2</sub> decrease associated with an increase of the <sup>13</sup>C isotopes during the day (particularly observed at the open swamp). Additionally these data are showing an increase of the CO mixing ratio between the samplings from morning and midday, whereas the results from the samples taken within the forest are characterised by a slight decrease.

**Figure 4.6.** Ground reference samples taken at the *Florana* nature reserve (Uppland / Sweden) within the open swamp (Morning 30, Midday 29 August 2001) and inside a wooded area (Morning 6, Midday 5 September 2001). Shown are the mixing ratios of CO<sub>2</sub> and CO and the  $\delta^{13}\text{C}$  values.

From the results two problems were identified: beside a frequent missing of the still shallow CBL during the morning flight flask pair differences appeared again. A systematic disturbance seemed to be likely, since most frequently the higher CO<sub>2</sub> mixing ratio was detected in the second flask. The chemical drying agent and an insufficient flushing rate were identified as the probable sources of the error and studied in laboratory experiments until the next campaign took place (see chapter 3.2.2.).

**4.1.4. Valencia Winter Experiment      16 November – 15 December 2001**  
**Final configuration of the modified flight sampling system**

Since air mass changes caused by the diurnal land-sea-wind circulation had to be expected similar as in summer, one focus of the investigation was the more distinct identification of the influence of advection. For this purpose the ground reference unit, enhanced by a wind vane, was first installed for several days within the rice fields. Later on ground level sampling was carried out in order to obtain specific source characteristics at the citrus orchard and beside a highway.

Due to the fact that the study sites were affected strongly by several disturbances, like point sources, advection and the high rate of urbanization, additional sampling and measurements should be carried out on a remote site. Investigations were therefore also performed at a mountain plateau, covered by macchia, the typical shrub vegetation community common around the Mediterranean Sea.

A further aim of the investigations was to obtain information, whether transformation processes or systematic differentiations occur between the flight samples and the data obtained from the ground reference examinations. For this experiment the rice field site provided the best conditions; because of the wide open area without obstacles and urban settlements low level flights could be realized.

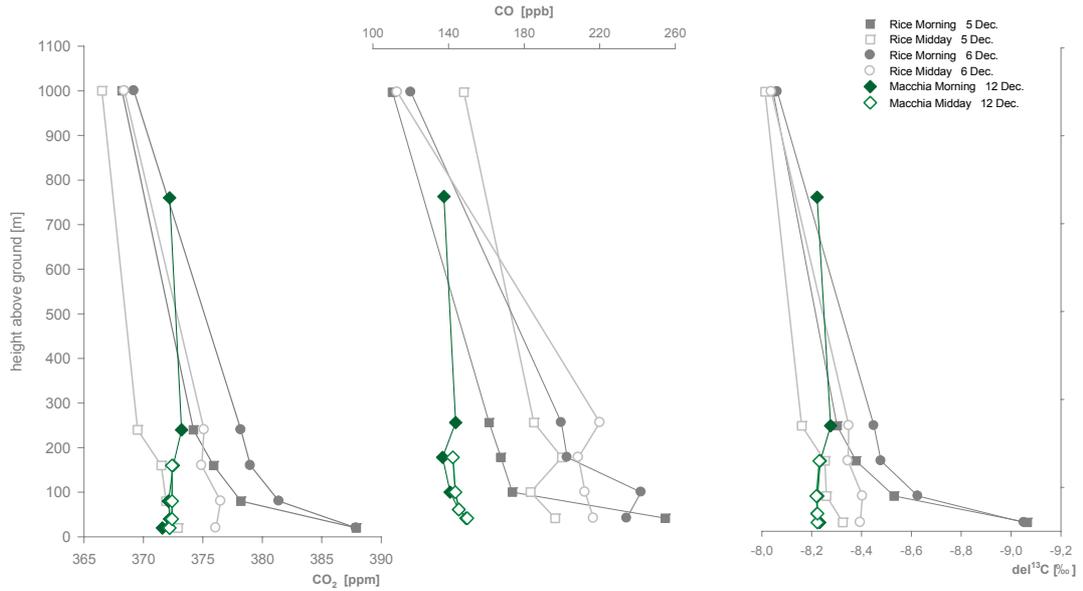

An overview of the observed trace gas mixing ratios and the delta<sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.5.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
<b>Lowest Level</b>	371 - 389	148 - 273	1830 - 1958	318 - 320	394 - 483	4.85 - 8.05	-8.215 - -9.087
<b>Free Troposphere</b>	366 - 373	110 - 202	1793 - 1851	318 - 323	439 - 480	4.85 - 5.18	-7.997 - -8.286

Heights LL and FT:      6 - 46 m / 825 – 1000 m      Number of flight days:      6      Number of profile sites:      3

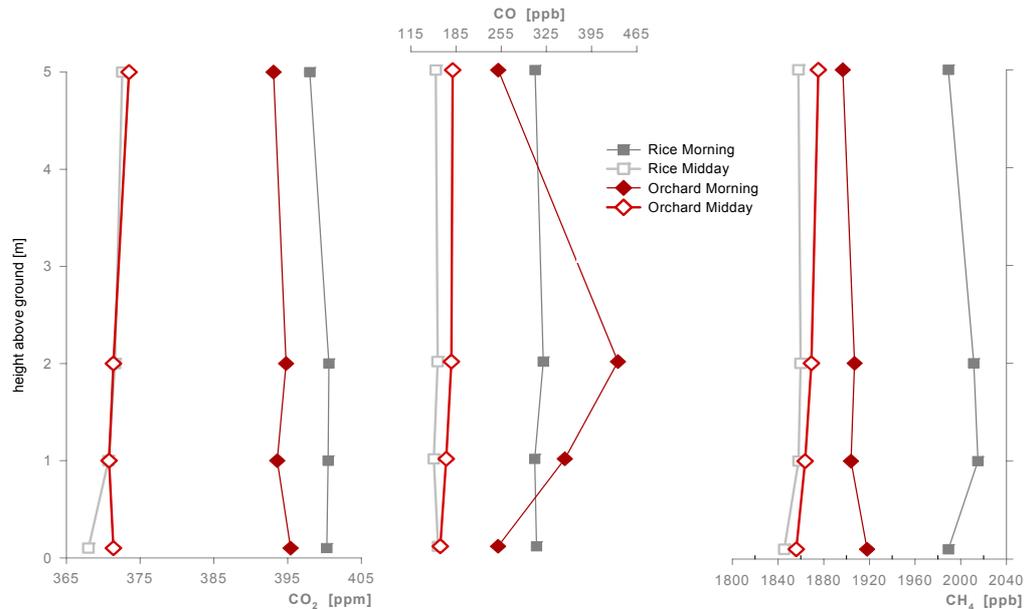

**Table 4.5.** Range between the maxima and minima of the mixing ratios and the delta<sup>13</sup>C values obtained from the flask sampling during the Valencia winter campaign.

Figure 4.7 presents the results from profile flights carried out on two consecutive days above the rice fields and from one day at the remote mountain site. The profiles at the rice field site are characterised by a decrease of the CO<sub>2</sub> mixing ratio and by delta<sup>13</sup>C values becoming less negative at all sample levels from the morning to the midday flight. However, for the CO mixing ratio 5 July, midday, at highest sampling level, an increase occurred.

**Figure 4.7.** Mixing ratio profiles from the Spanish winter experiment (16 November to 15 December 2001) above the *Rice* field area and at the remote mountain site ‘Cortes de Pallás’ (labelled ‘*Macchia*’). Shown are the CO<sub>2</sub> and CO mixing ratios and delta <sup>13</sup>C values.

The profiles from the mountain site are very similar in the morning and at noon. But it has to be mentioned that because of technical problems the morning flight started 3 hours later than the morning flights above the rice field area.

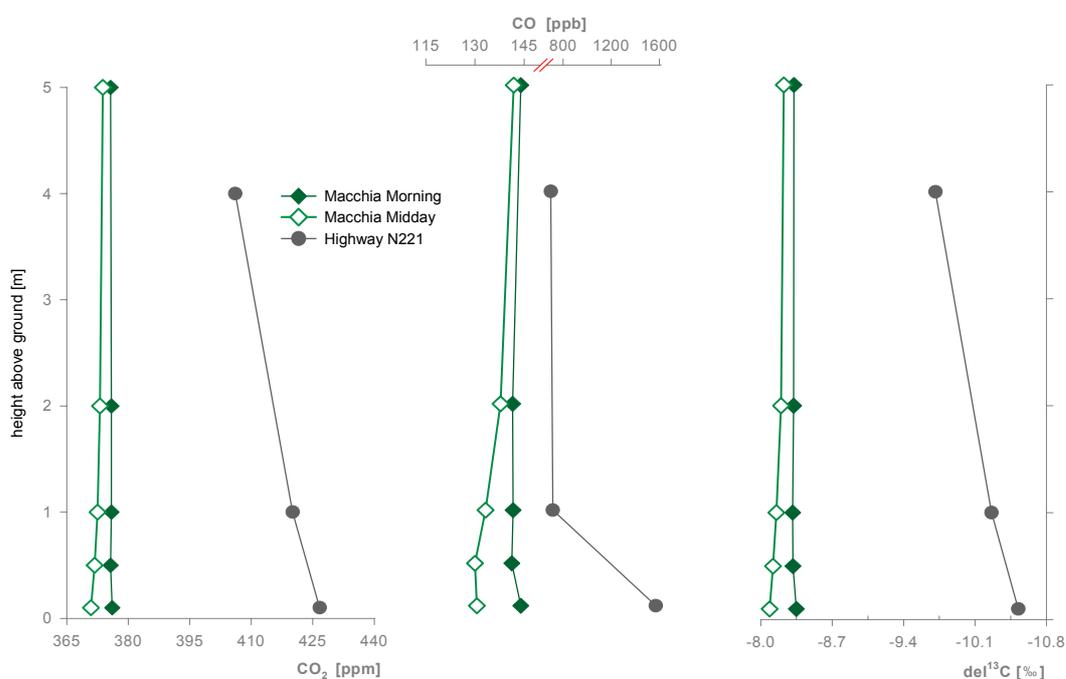

**Figure 4.8.** Mixing ratios of CO<sub>2</sub>, CO and CH<sub>4</sub> from samples taken at the *Rice* field location and inside a citrus *Orchard* (Morning: 3 December 2001, Midday: 30 November 2001; Valencia / Spain).

Ground reference samples were taken at four different sites: Figure 4.8. presents the results from the rice field location and a citrus orchard, whereas figure 4.9. shows the sampling results from the remote mountain site and close to the highway.

For the rice and the orchard location a decrease of the CO<sub>2</sub> mixing ratio can be observed for the samples from before sunrise to around noon. This tendency can be recognized also for the other trace gas species (see data tables for reference). Remarkable are also the increase of the CO mixing ratio within the orchard and the high CH<sub>4</sub> mixing ratio at the rice field site in the morning.

Figure 4.9. compares the data from the ground reference samplings at the remote mountain site and beside a highway near Valencia. Remarkable are the high mixing ratios of CO<sub>2</sub> and CO in particular at the surface level near the highway, which is also associated with a low <sup>13</sup>C isotope presence. In contrast the mountain site samplings are characterised by clearly less negative delta<sup>13</sup>C values and lower CO<sub>2</sub> and CO mixing ratios. A slight decrease of the mixing ratios can be recognized until noon, which is associated with an increase of the relative fraction of the <sup>13</sup>C isotope.

**Figure 4.9.** Results of the samples taken at the 'Macchia' remote mountain site and close to the 'Highway N221' (Valencia / Spain). Shown are the mixing ratios of CO<sub>2</sub> and CO and the delta<sup>13</sup>C values.

**4.1.5. The Netherlands Winter Experiment      14 January – 10 February 2002**  
**Test of the improved sampling strategy**

Very intensive agriculture and a high level of urban sprawl are characteristic for the field site in the central part of The Netherlands.

Specific Intentions

From the results of the earlier campaigns it had become obvious that not only the instrumentation threatened the scientific goal but also changing air masses. With respect to the basic aim of the project – the estimation of a regional carbon budget and the qualification and quantification of sources and sinks – the suitability of the chosen approach is questionable. On one hand, it is fundamental for the identification of different contributions to the final budget that the characteristics of the individual sources and sinks should be distinguishable from each other. Therefore a background mixing ratio has to be found, from which contamination events and the carbon fluxes directed in- or outside the regional pool could be determined.

Another important question was to identify the sites and sampling heights which are characteristic for the entire region to be described.

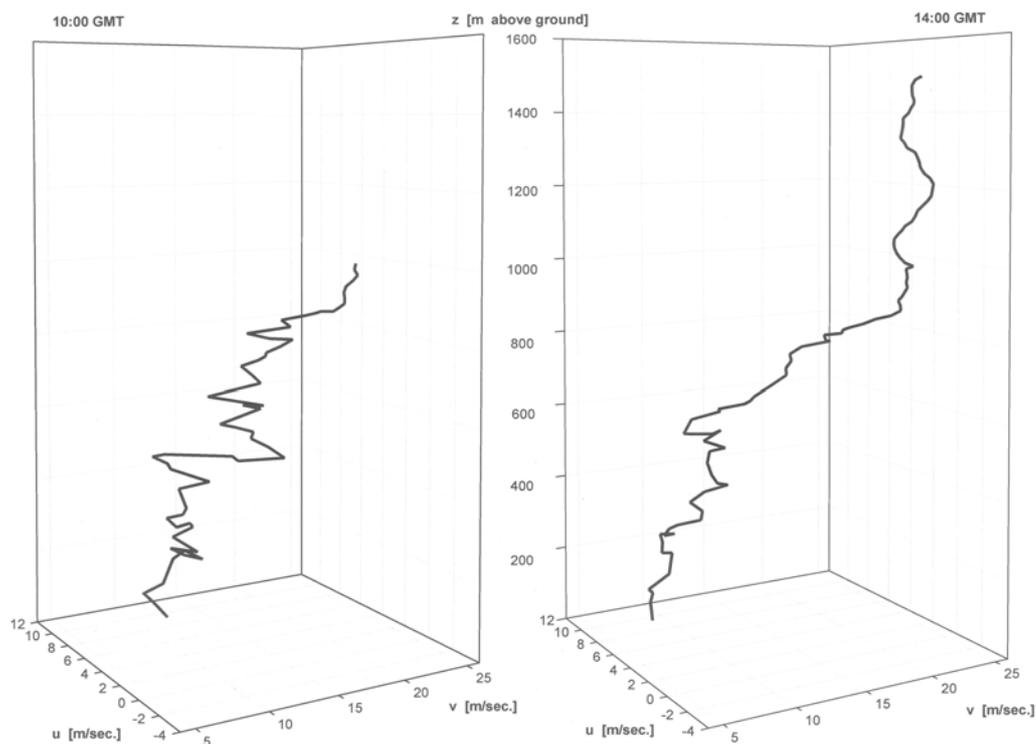

One reaction to accommodate these requirements was to implement the ground reference unit for finding the trace gas characteristics of the major land classes. A second attempt focused on the proper flight sampling strategy itself: accomplished by the integration of an adapted investigation approach.

*FLIGHT AND SAMPLING STRATEGY*

Aim of the new strategy is to get additional information with respect to transformation processes due to the exchange of the local air mass by advection. The basic idea is to combine local results from sampling above characteristic land use classes with data representing the regional scale as a whole, by carrying out flights along a transect orientated at the prevalent wind direction. Compared to the common strategy, of measuring one vertical profile around a central point of the study region, the implementation of the new attempt is more complicated. The idea was to sample three individual sites across the study region, following a line from west to east: marshland, agricultural land and forest.

## VARIABILITY OF THE WIND

An additional attempt focused on better wind field information. Because of air mass changes with unknown origin most frequently the sampled air probes are not useable for budgeting. Therefore, in a test mode vertical profiles should also include the wind vector.

**Figure 4.10.** Wind velocities in u- and v-direction recorded by the MFP 'Sky Arrow' during the combined flight section above the *Forest* site on 29/01/ 2002 (The Netherlands).

Data from GIOLI, B. & B. DE MARTINO

Unstable conditions were predominant during the complete campaign. In particular a very inconsistent wind field at the spatial as also at the temporal scale became obvious, as documented by the records of the MFP when performing the combined vertical profiles (see figure 4.10.).

An overview of the observed trace gas mixing ratios and the delta<sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.6.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
<b>Lowest Level</b>	378 - 396	165 - 346	1859 - 2126	318 - 321	514 - 631	4.92 - 7.15	-8.390 - -9.465
<b>Free Troposphere</b>	372 - 379	126 - 203	1807 - 1846	318 - 319	505 - 559	4.82 - 5.18	-8.127 - -8.489

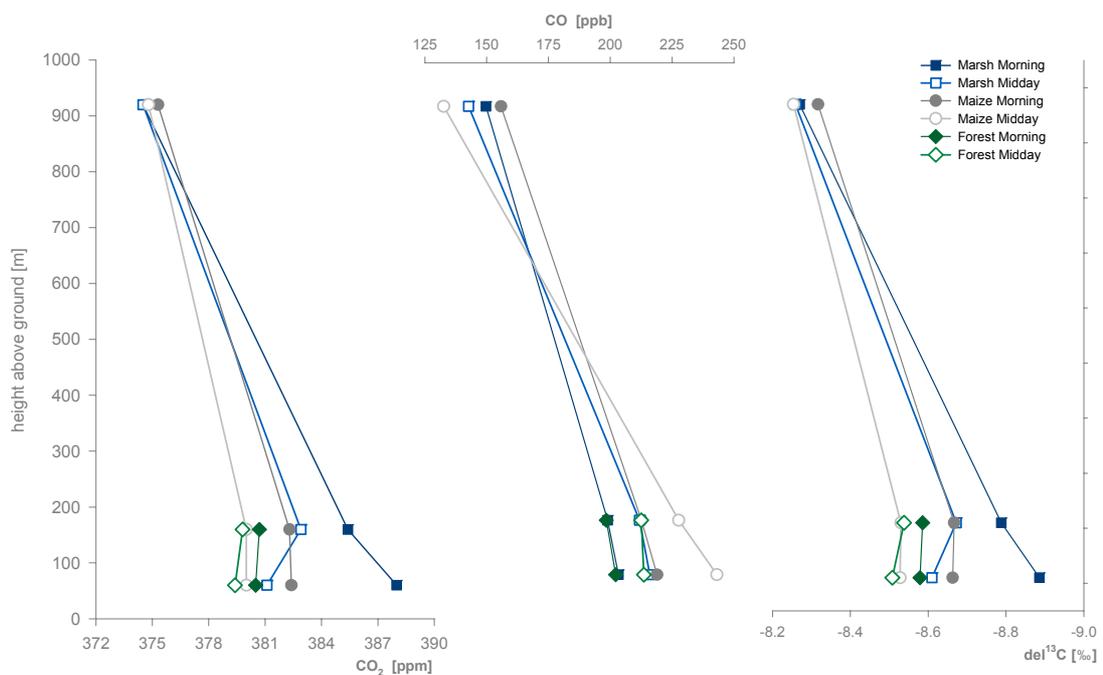

Heights LL and FT: 60 m / 915 m

Number of flight days: 5

Number of profile sites: 3

**Table 4.6.** Range between the maxima and minima of the mixing ratios and the delta<sup>13</sup>C values from the flask sampling during the winter campaign in The Netherlands.

The two flights presented in figure 4.11 were performed on 2 February 2002. All three sites were sampled uninterrupted, starting with the 'Marsh' location (north of the Cabauw Tower; morning: 10:00 UTC, midday: 14:20 UTC), followed by the 'Maize' site (morning: 10:50 UTC, midday: 15:10 UTC) and finished at the 'Forest' (morning: 11:30 UTC, midday: 16:00 UTC; here only the two lowest heights were sampled, caused by the flight time capacity of the aircraft). Obvious are the decrease of the CO<sub>2</sub> mixing ratio and the shift of the delta<sup>13</sup>C to less negative values between both flights through the entire profile, whereas the CO mixing ratio at the lowest two sample levels increased. The highest reduction of the CO<sub>2</sub> mixing ratio in the lower atmosphere was observed at the 'Marsh' site. For all trace gases the values measured within the free troposphere were lower than the mixing ratios sampled beneath.

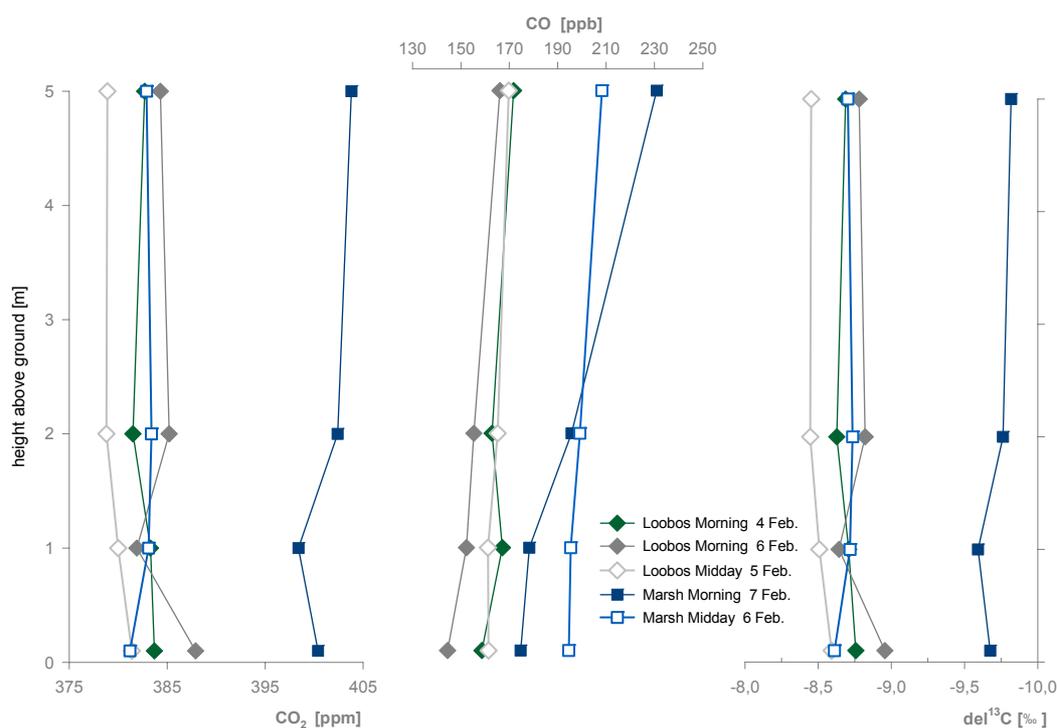

**Figure 4.11.** CO<sub>2</sub> and CO mixing ratios and delta<sup>13</sup>C values from profile flights on 2 February 2002 above the 'Marsh' [Cabauw], the 'Maize' and the 'Forest' site (The Netherlands).

Additional ground reference measurements and samplings were carried out at all three different land use types. Results from the flask sampling performed at the 'Marsh' location and within the forest nearby the 'Loobos Fluxnet Tower', a few kilometres north-east of the 'Maize' reference site are displayed in figure 4.12.

Morning samples at the forest site were taken on two different days (4 and 6 February 2002), both around 6:40 UTC. Midday sampling took place on 5 February around 13:00 UTC. Samples at the 'Marsh' site were performed on 6 (midday) and 7 February 2002 (morning) at the same local time as at the forest location.

A large difference of the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values between the morning and midday data at the 'Marsh' site is obvious. On the other hand the decrease nearest the surface, observed during the day, is smaller in the forest than the difference that can be recognized between the samples taken in the morning of the 4 and the 6 February 2002.

Compared with the data from the flights similar behaviour is obvious, reflecting in particular the tendency of a decreasing CO<sub>2</sub> mixing ratio and an increase of the <sup>13</sup>C isotopes during day time.

**Figure 4.12.** CO<sub>2</sub> and CO mixing ratios and delta<sup>13</sup>C values from ground reference samplings carried out in a forest nearby the 'Loobos Tower' and within the 'Marsh' area north of the Cabauw Tower (The Netherlands).

#### 4.1.6 Lazio Summer Experiment

27 May – 27 June 2002

The experiment took place in the northern part of the Lazio region, Italy. Mostly forested mountain ridges and intense agriculture in the plains west of the mountains are characteristic for this study area.

A specific goal of this campaign was to proceed with the ‘transect approach’ (see chapter 5.4.2.). Additionally the examination should be extended by studies regarding the development of distinct layers [MUSCHINSKI & WODE 1998]. To accomplish this it was aimed to sample at an isolated site, where during night time a clear stratification of layers from different origin would occur. Therefore flights were carried out within and above a bowl-shaped valley near the settlement of Orvinio.

#### Observations

Because of several technical problems flights could be performed on two days only in the morning and in the afternoon. Thus only singular events have been investigated. An overview of the observed trace gas mixing ratios and the delta<sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.7.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
<b>Lowest Level</b>	366 - 410	130 - 369	1796 - 1884	318 - 320	542 - 670	5.16 - 5.76	-7.775 - -9.840
<b>Free Troposphere</b>	373 - 375	101 - 682	1778 - 1801	317 - 318	534 - 1056	5.03 - 5.15	-8.124 - -8.209

Heights LL and FT:

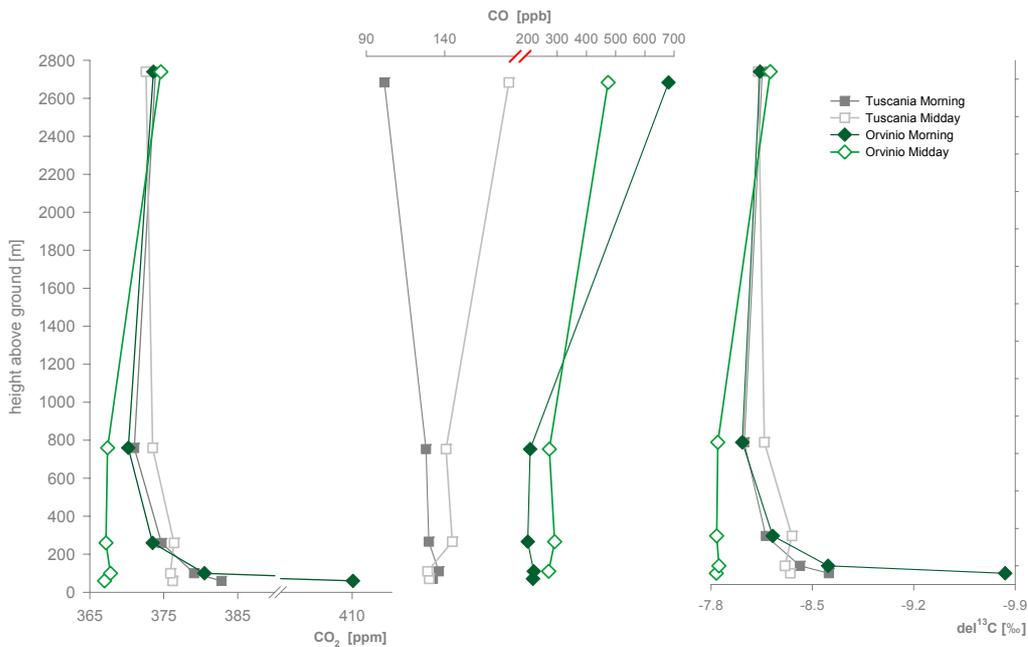

50 - 80 m / 3000 m

Number of flight days: 2.5

Number of profile sites: 2

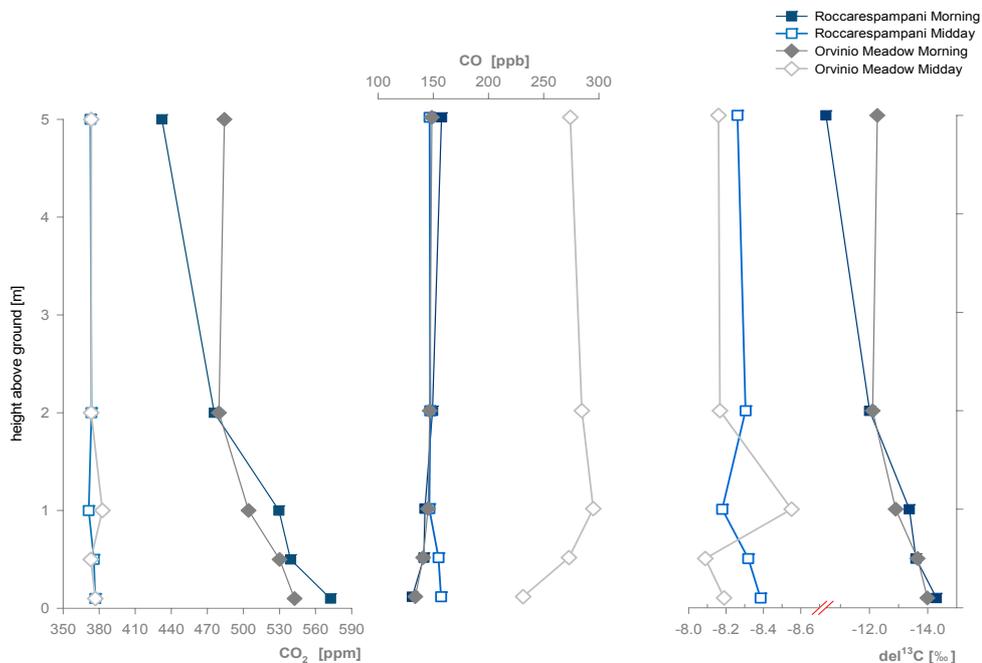

**Table 4.7.** Range between the maxima and minima of the mixing ratios and the delta<sup>13</sup>C values obtained from the flask sampling during the airborne campaign in the Lazio region (27 May to 27 June 2002).

Figure 4.13. presents the flight profiles from both locations. For the CO<sub>2</sub> mixing ratio at the two lowest levels a decrease is recognizable between the morning and the midday flight, distinct particularly at the Orvinio location, associated with a relative increase of the <sup>13</sup>C isotope fraction. For CO no clear decrease is visible. Instead, a very high CO mixing ratio was found above the mountain site, as well as a large difference between the morning and the midday flight at both locations within the free troposphere. A diurnal variation of the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values becomes also obvious by the ground reference samples, however a differentiation between both sites is not so clear as for the flight data.

**Figure 4.13.** CO<sub>2</sub> and CO mixing ratios and delta<sup>13</sup>C values obtained from the profile flights performed at the 'Tuscania' [Roccarespampani] site on 15 June and above the remote mountain location 'Orvinio' on 18 June 2002 (Lazio / Italy).

The highest values could be observed closest to the ground (see figure 4.14.). Contrary to the general behaviour of CO<sub>2</sub> and delta<sup>13</sup>C at the mountain site the CO increased strongly from the morning to the midday sampling; but a distinct jump upwards was observed for the 1 m samplings in CO<sub>2</sub> and delta<sup>13</sup>C.

**Figure 4.14.** Ground reference samples taken beside the tower at the 'Roccarespampani' forest site and above a Meadow within the valley of 'Orvinio' (Lazio / Italy). Shown are CO<sub>2</sub> and CO mixing ratios and the delta<sup>13</sup>C for samples taken before sunrise (Morning) and around noon (Midday).

**4.1.7 The Netherlands Summer Experiment**  
**Enhancement of the improved sampling strategy**

**10 – 28 July 2002**

Main emphasis was to improve the enhanced ‘transect approach’ sampling strategy (see ‘The Netherland Winter Experiment’), that aims to combine the quantification and qualification of the most important sources and sinks with the carbon budget synopsis for the entire region. Also specific attention was given to a comparison of the winter and summer results, in particular with respect to differences of the mixing ratios and the responsible processes.

Observations

An overview of the observed trace gas mixing ratios and the delta<sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.8.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
<b>Lowest Level</b>	359 - 403	132 - 264	1855 - 2166	319 - 327	561 - 684	5.16 - 5.66	-7.536 - -9.566
<b>Free Troposphere</b>	364 - 370	113 - 151	1776 - 1819	318 - 319	556 - 649	5.13 - 5.31	-7.716 - -8.041

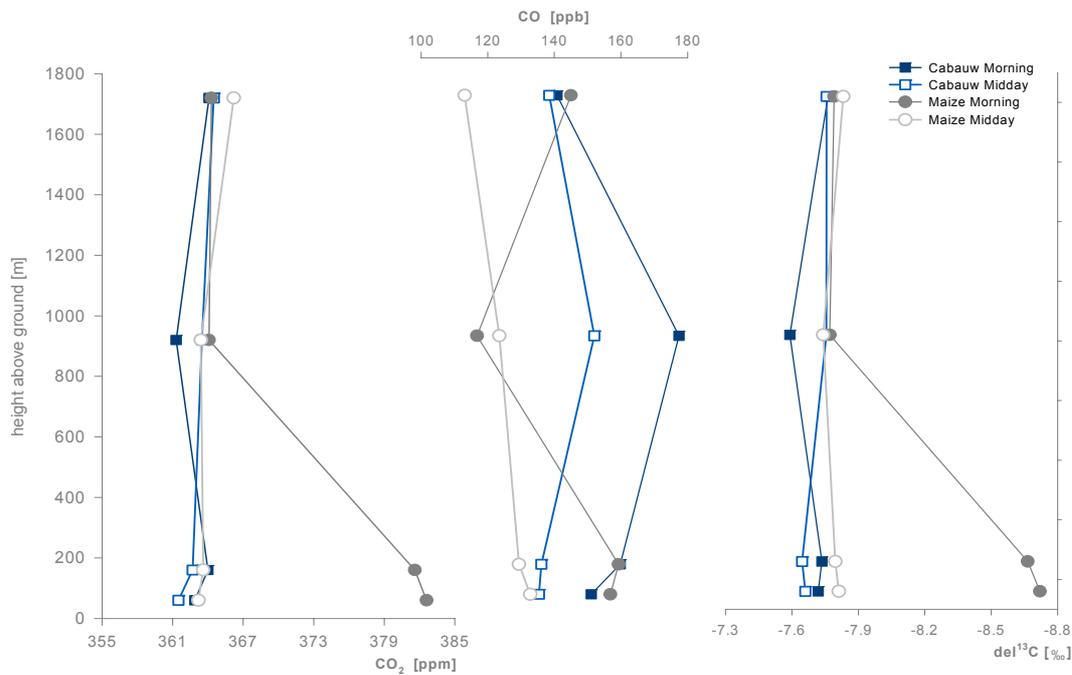

Heights LL and FT: 60 m / 1700 - 1800 m      Number of flight days: 3      Number of profile sites: 3

**Table 4.8.** Range between the maxima and minima of the mixing ratios and the delta<sup>13</sup>C values obtained from the flask sampling during the summer campaign in The Netherlands (10 to 28 July 2002).

An example for the flight profiles is given in figure 4.15 for the 15 July above the marshland north of the Cabauw Tower and near to the ‘Maize’ reference site at around 8:00 UTC at the ‘Maize’ site and at 9:00 UTC at the ‘Cabauw’ location, as well as at 12:45 UTC (‘Maize’) and at 13:50 UTC (‘Cabauw’).

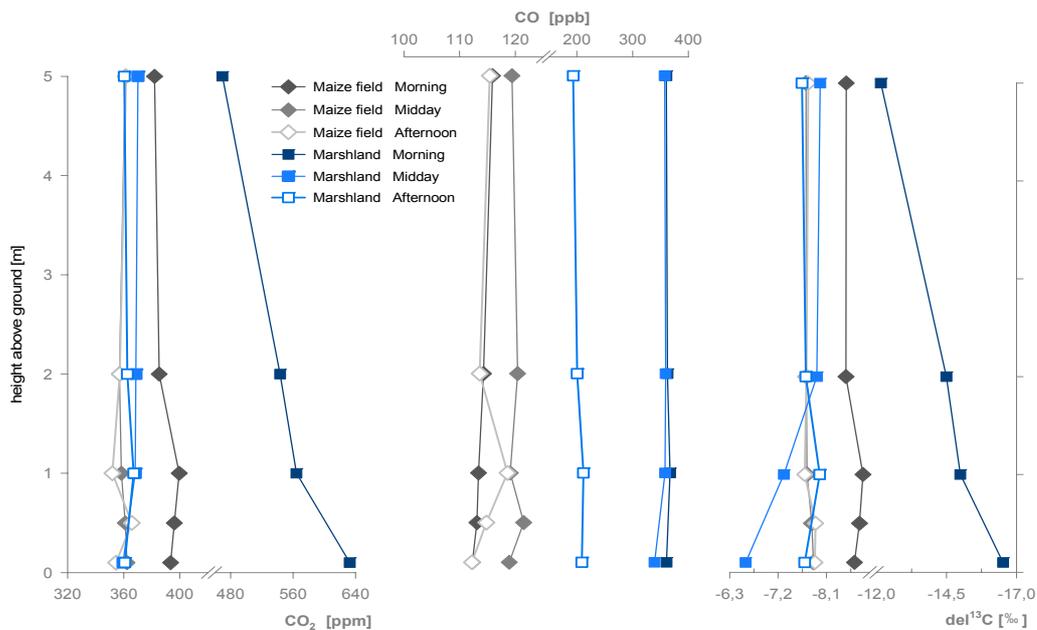

Except for the two lowest morning sample levels at the ‘Maize’ site only slight differences can be recognized in the profiles of the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values. But contrary to these parameters great variability is obvious for CO. Remarkable is a clearly reduced mixing ratio sampled at the level of 915 m height above the ‘Maize’ location, and a decrease between the morning and the midday sampling within the free troposphere.

Ground reference sampling was again carried out inside and above a maize field (18 July; 4:00, 11:00 and 15:30 UTC), at the same location as in winter for the marshland north of the Cabauw Tower (28 July; 4:00, 12:00 and 16:30 UTC).

**Figure 4.15.** CO<sub>2</sub> and CO mixing ratios and delta<sup>13</sup>C values from profile flights on 15 July 2002 above the marshland north of the *Cabauw* Tower and over the agricultural site nearby the 'Maize' ground reference location (The Netherlands).

The results in figure 4.16 point to very high mixing ratios of CO<sub>2</sub> and CO combined with a low <sup>13</sup>C isotope fraction for the morning at the marshland site. At both locations during day time CO<sub>2</sub> mixing ratios decreased while the fraction of the <sup>13</sup>C isotope increases. Thereby the highest <sup>13</sup>C values were recorded nearest to the surface over the marshland around midday.

**Figure 4.16.** Mixing ratios of CO<sub>2</sub> and CO and delta<sup>13</sup>C values inside the *Maize* field on 18 July 2002 and on 28 July 2002 above the meadow site *Marshland* (The Netherlands).

**4.1.8. SPA<sup>13</sup>CE Thuringia Summer Experiment**  
**Combined ground level and flight investigations**

**6 – 15 August 2002**

During the first two weeks of August an intensive measurement activity focussing on different scales has taken place in and over the Hainich National Park.

Aim of the SPA<sup>13</sup>CE (Soil Plant Atmosphere <sup>13</sup>C Exchange) experiment was to monitor the isotope characteristics from the microbiological level up to the regional and continental scale over a period of several days. Within the project vertical profiles of mixing ratios were measured above the Hainich on the 6, 14 and 15 August 2002 twice a day.

**Table 4.9. Weather conditions recorded at the Hainich Tower 14 and 15 August 2002**  
 (Temperature at 2 m height, wind velocity and direction at the top of the tower)

	Temperature [°C]		Wind velocity [m/s]		Wind direction
	Max.	Min.	Max.	Min.	Mean
14 August 2002	19.5	14.4	4.1	1.3	WNW
15 August 2002	22.8	16.8	2.8	0.8	N

The experimental strategy was, to jointly analyse for several ecosystem levels with the intention to obtain insight into the isotopic composition at different spatial scales. Therefore a basic need was to close the gap between the tower and the flight measurements, which could be achieved by lowering the lowest flight level to the height of the uppermost tower platform (see also the investigation carried out during the ‘Valencia Winter Experiment’, chapter 4.1.4. and 4.2.2.).

An overview of the observed trace gas mixing ratios and the delta<sup>13</sup>C values at lowest flight level and within the free troposphere is given in table 4.10.

	CO <sub>2</sub> [ppm]	CO [ppb]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	delta <sup>13</sup> C [‰]
<b>Lowest Level</b>	362 - 373	90 - 144	1797 - 1877	319 - 321	510 - 538	5.18 - 5.50	-7.559 - -8.125
<b>Free Troposphere</b>	364 - 371	66 - 135	1748 - 1849	318 - 319	522 - 535	5.07 - 5.61	-7.822 - -7.972

Heights LL and FT: 60 m / 1500 m

Number of flight days: 3.5

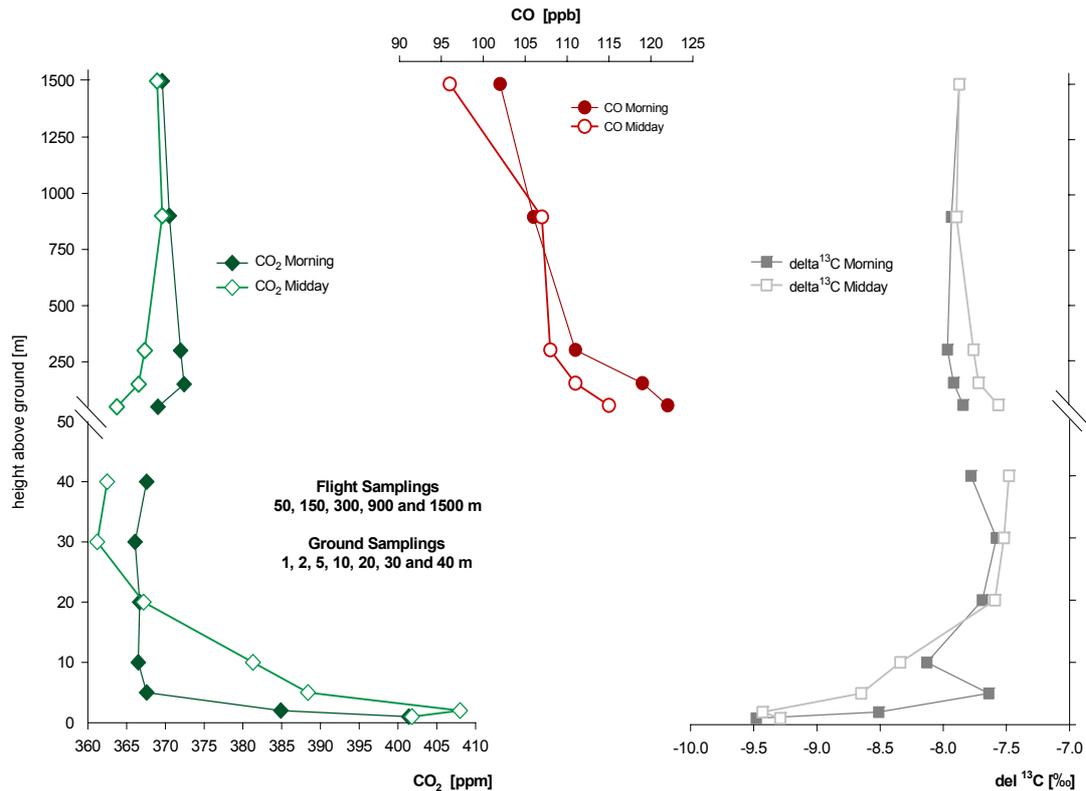

Number of profile sites: 2

**Table 4.10.** Range between the maxima and minima of the mixing ratios and the delta<sup>13</sup>C values during the SPA<sup>13</sup>CE experiment performed on 6, 14 and 15 August 2002 above the Hainich and from a singular flight on 9 August 2002 for the ‘Holzland’ site south-east of Jena.

Quite similar results for the CO<sub>2</sub> mixing ratios and the delta<sup>13</sup>C values were obtained by the comparison of the concurrently performed tower and flight

samplings. For the first time the gap could be closed and a direct upscaling was possible from the local to the regional scale.

Additional emphasize of the flight investigations was to monitor the gas mixing ratios and isotope composition on consecutive days. A detailed study of the vertical profile structure, with respect to the rate of mixing, was one more specific aim. Another focus was on to examinations of the vertical structure of the CBL with respect to mixing processes.

**Figure 4.17.** Profiles of CO<sub>2</sub> and CO mixing ratios and delta<sup>13</sup>C values on 15 August 2002 from ground level to the free troposphere at the *Hainich* (Germany). Near surface samplings were carried out by A. Knohl.

### Observations

The results from both the flight and groundbased samplings, performed simultaneously on 15 August 2002, are presented in figure 4.17. Firstly, it should be recognized that the profiles taken by the tower and by the flight samplings for the same height level correspond very well. From the 30 m level upwards both profiles show a distinct decrease of the CO<sub>2</sub> mixing ratio during the day while the relative fraction of the <sup>13</sup>C isotope is increasing. A remarkable observation from the

flight profile is the stability of the CO<sub>2</sub> mixing ratio and of the delta<sup>13</sup>C values with increasing height, starting from the 150 m level, whereas the CO mixing ratio decreases significantly between both samplings as well as with increasing height. In contrast to the observations made on this day data from the day before and from 6 August differ strongly regarding the mixing ratios and the delta<sup>13</sup>C values. Stratification and the presence of distinct layers during the whole day were observed on all days (see figures 4.28. and 4.29.).

## 4.2. Interpretation of the Results

To reach the primary goal of RECAP, the characterisation of the different study regions, the structure of this section follows the division into different zones.

From the first analysis of trace gas mixing ratios it became obvious that frequently the fundamental assumptions for the CBL budgeting are not met even after major modifications of the sampling system and of the sampling strategy. Therefore, the results will be interpreted now in a more qualitative way

### Southern Europe

#### 4.2.1. Valencia Summer Experiment

17 June – 7 July 2001

The high night time values of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O observed in the ground reference samples (see figure 4.2) might be caused on one hand by the occurrence of stratification within the canopy. On the other hand, an enhanced activity of soil related processes, resulting from higher soil moisture, is most likely. Reduced microbial activity, caused by the drying of the soil, and forced mixing by turbulence during day time should effect a decreasing of the mixing ratios on 5 July 2001. Contrary to this assumption the N<sub>2</sub>O profile shows an increase of the mixing ratio, which can be explained by an exchange of local air by air that has passed recently irrigated orchards. Since all apricot trees of the orchard were trimmed between both sampling events the CO<sub>2</sub> uptake was less than the days before.

A decrease of the CO<sub>2</sub> mixing ratio from the morning to the midday flights was detectable at both locations: For the rice field data a significant contribution by vertical mixing can be excluded. Because of the large variability seen for the entire profile a combination of CO<sub>2</sub> uptake by plants and advection of CO<sub>2</sub> poor marine air seems most probable.

The effect of a mesoscale circulation becomes evident when inspecting the CO<sub>2</sub> mixing ratio at the highest flight level, where an increase is obvious between the morning and the midday flights. In the morning the inflow of marine air in the upper branch of the night time circulation is reflected, while during midday air originates from inland, as in the late morning hours the night time off shore wind was replaced by a flow directed to the inland at the surface.

Under such conditions a budget estimate is not possible, since the air masses are rather independent because of their different origin and evolution.

Since the air mass exchange also affects the uppermost level it is dangerous to use this 'free troposphere sample' as a background value for the budgeting.

Even though the modified sampling unit worked well the anticipated improvements regarding a reduction of the flask pair deviation by adapting the sampling flow rate could not be fully achieved. Most probable reasons for this remaining difference are the heterogeneity of the land use and, in particular, strong trace gas point sources because of biomass burning scattered around the orchards. Because of these major local disturbances a regional characterisation with respect to the carbon budget cannot be accomplished by flask sampling.

#### **4.2.2. Valencia Winter Experiment                      16 November – 15 December 2001**

By analysing the results from flight and near surface sampling the presence of a mesoscale circulation scheme, however less developed than in summer, can be detected. Remarkable are the high mixing ratios above the rice fields at the lowest flight level, probably due to an outflow towards the sea - bearing air of urban origin. In contrast the data from the remote mountain site are characterised by only slight variability, which might be representative for 'undisturbed' rural conditions. A minimal plant activity is recognizable from the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values near to the ground: a slight CO<sub>2</sub> increase during night, coming along with more negative delta<sup>13</sup>C values. That the flight profiles are showing no clear signal might also be caused by the late time of the morning flight. Compared with the other sampled locations the site could be characterised as a remote area, only slightly changed by human activities. Because of this distinct character it could provide representative background data for typical mediterranean vegetation.

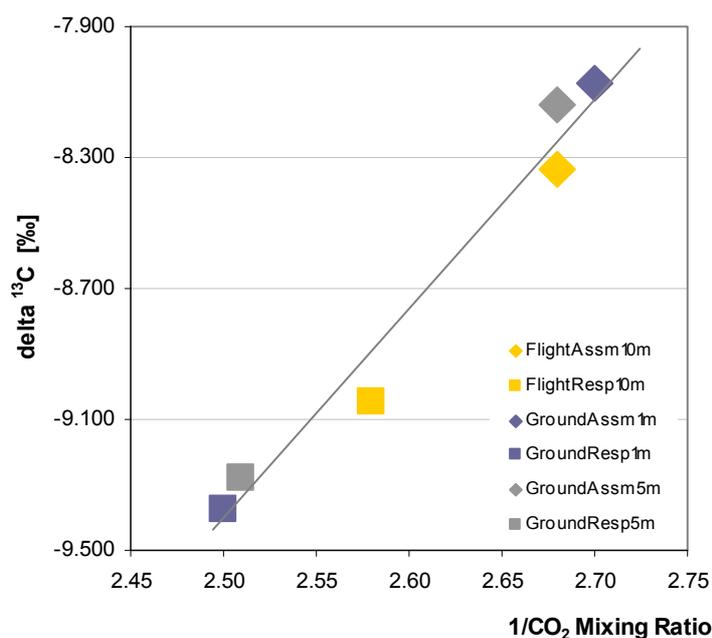

A remarkable feature of the near surface reference air samples in the orchard is the CO increase below and inside the still foliated canopy of the trees. Since this behaviour is only recognizable for CO probable is the capture of a smoke plume from the biomass burning around this sampling spot. That the CO<sub>2</sub> mixing ratio is

less affected might be caused by enhanced values from soil respiration captured in a layer close to the ground, which masks the increase in the next upper levels.

The elevated CH<sub>4</sub> mixing ratio found at the rice field site during night time is reflecting the contribution of methanogenic bacteria, which were still active in the mud.

From the enhanced sampling near to the surface, in particular from the activity close to the highway, additional information could be obtained with respect to advection processes. By comparison of the individual signals from the reference sites a strong change in air mass characteristics became evident. Data from the sampling close to the highway exemplifies the fossil fuel contribution (see figure 4.9).

Around the reference tower in the rice field site lowest level flights (<10 m above ground) could be performed. By closing the gap to the near surface measurements the comparison of the reference samples with the flight samples became possible, as well as an estimation of effects caused by using different sampling equipment and schemes. Results from the near surface sampling and from airborne samples taken at lowest flight level are displayed as 'Keeling plot' in figure 4.18. The source signal was calculated to be -25.5 ‰, which is in the typical range for C3 vegetation.

**Figure 4.18.**

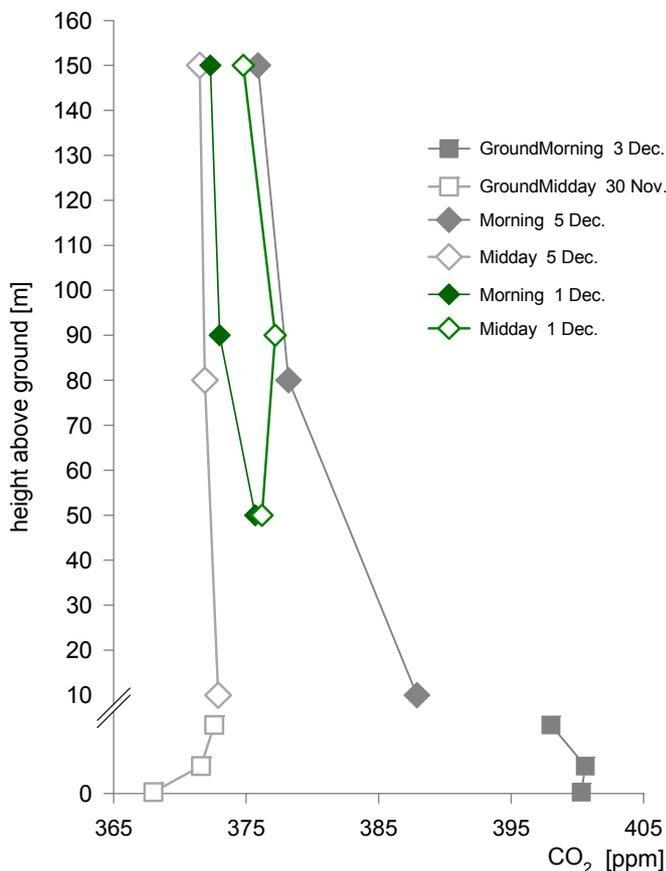

delta<sup>13</sup>C and CO<sub>2</sub> mixing ratios sampled at two heights by the ground reference unit and from the lowest flight level above the *Rice* field site (Valencia / Spain).

Source -25.5‰, R<sup>2</sup> = 0.9714

Taking into account that the airborne samples were taken delayed, shortly after sunrise, and that the flight data are representing a larger area – the track around the tower was approximately 1000 x 1000 m, with slightly different surface conditions like water cover, plant density, etc. - the results from both systems agree very well (see for further description also in the documentation folder figures 5 and 6, and the flight scheme).

Additionally the very shallow stable layers in the morning, containing the mixture of the upwind emission sources, could be sampled.

Because the effect of air mass exchange by advection becomes more efficient with increasing altitude a budget which bases solely on the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values obtained from the flight samplings might underestimate the contribution by plant activity. Thus only by the combination of flight and additional ground level measurements and air samplings the mandatory information can be achieved.

**Figure 4.19.**

CO<sub>2</sub> mixing ratios from flask samples at ground level and from two different flight days above the *Rice* field site (Valencia / Spain).

The lowest flight level above ground was on 1 December 50 m, which could be reduced down to 10 m on 5 December.

#### 4.2.3.1. Lazio Summer Experiment

27 May – 27 June 2002

Although profiles could be taken only on one day each for both locations interesting observations were made: For both sites a well developed change of the CO<sub>2</sub> mixing ratio was recorded. When comparing the data from the samplings close to the ground only slight differences in the mixing ratios of CO<sub>2</sub> and delta<sup>13</sup>C became obvious. In contrast the results from the flights are clearly different between both locations. The main reason was the relative small extension of the Roccarespampani forest, which contributed only little to the flight profile. Regarding the differences obtainable at both profile locations it has to be taken into account that at the mountain site the meadows and the forest at the ridges were still assimilating, whereas most of the agricultural areas around the Roccarespampani forest had just been harvested or ploughed.

Of special interest are the observed high CO mixing ratios at the mountain site. Especially one 'stable layer' could be identified by the free troposphere sample, indicating that the CBL was covered by a significantly different air mass. From the analyses and by the comparison of the trace gases and the delta<sup>13</sup>C values (see figures 4.13. and 4.20.) this air mass could be identified as one with exceptional composition: the covariance of low SF<sub>6</sub>, but high CO and H<sub>2</sub> mixing ratios indicates as most probable source smoke from a forest fire (see also 4.2.3.3 'Back Trajectory Calculations').

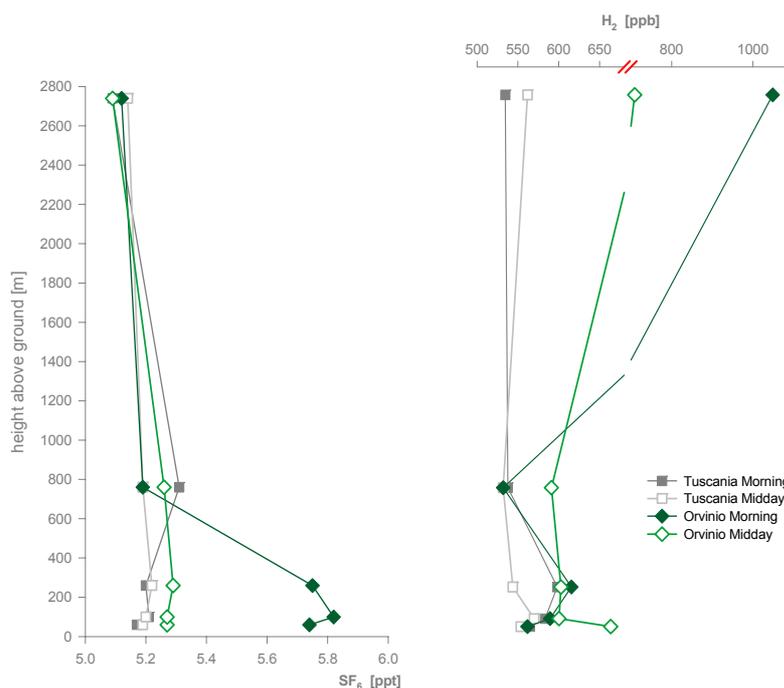

Figure 4.20.

SF<sub>6</sub> and H<sub>2</sub> mixing ratios obtained from flight profiles over the 'Tuscania' site on 15 June and above the remote mountain location 'Orvinio' on 18 June 2002. (Lazio / Italy)

An increase of the mixing ratios is also recognizable during daytime at the lower levels, which will be affected by entrainment of the contaminated air.

A high diurnal variability could be also observed within the free troposphere at the 'Tuscania' flight location; however the difference through the entire profile is less developed than at the mountain site. In consequence the suitability of the free troposphere samples to provide background data has to be checked individually.

One further remarkable result from the near surface sampling at the 'Orvinio' site was the increase of the CO mixing ratio during day time, associated with a clear upward jump of the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C value obtained from the flasks sampled at 1 m height. During the period of sampling a meadow was mowed in a few hundred meters distance. Probably the samples were contaminated by advected exhausts of the tractor.

The development of a stable, i.e. stratified layer is conceivable from the comparison of the reference and the flight data: the lowest flight level reflects the characteristics of the meadows, whereas the results from the next upper sample heights indicate air from the forested slopes (not shown; see the data table in the documentation folder). This suggests that a first nocturnal boundary layer was covered by at least one more air mass draining downhill from the ridges. The layer structures inside the valley were dissolved during day time, most probably from circulation driven by thermal convection and overflows over the ridges.

A comparison of the results from Italy with the summer campaign in the Valencia region is problematic: in Italy both locations were sampled only on one day and the background values from the free troposphere are affected by forest fire smoke. On the other hand the results from the campaign in Spain are as well unique, because of the influence from local biomass combustion and the sea breeze circulation.

#### **4.2.3.2. Inverse Studies**

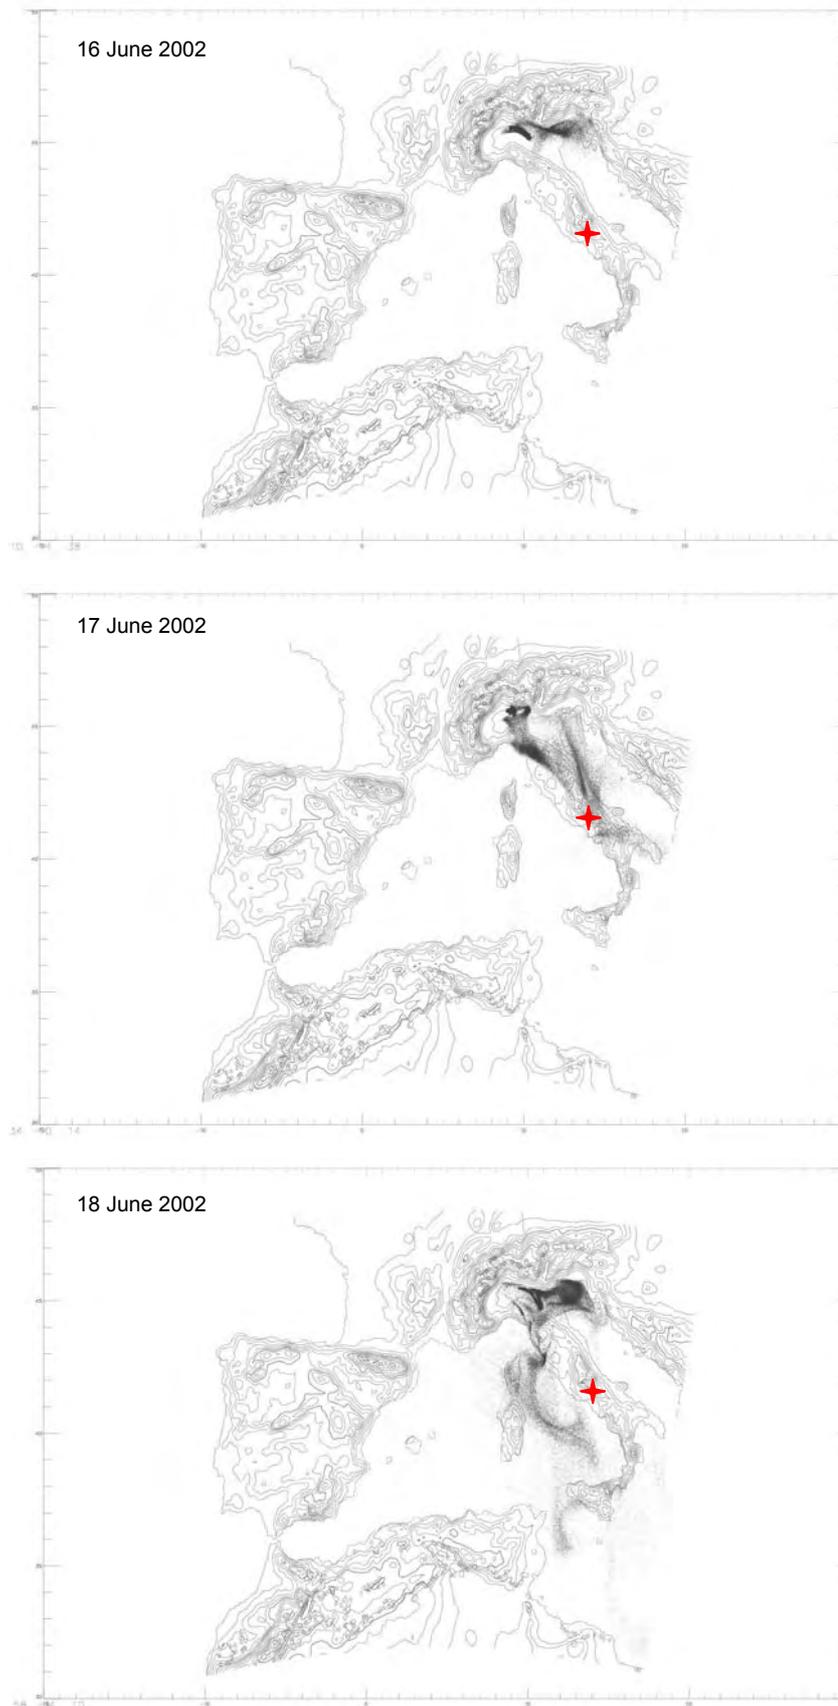

One RECAP goal was to use the field data for modelling studies. Modelling in this thesis offers the opportunity to present two aspects: 1) the use of models for the spatial assignment of source areas, and 2) the evaluation of model results by multiple tracer analyses. For example, which uncertainties occur when using only CO<sub>2</sub> data as input parameter for the interpretation of modelling? The answer can be with a mesoscale dispersion model.

Since it became obvious from the multiple tracer analyses, that often distant source areas and formation processes seems to be responsible for the trace gas mixing ratios, a second case study presents modelling including back trajectory calculations.

#### 4.2.3.2. Mesoscale Dispersion Model

High resolution calculations were performed by GORKA PÉREZ-LANDA from the CEAM in Valencia using the mesoscale model MM5. Therefore a potential source was defined in Milano (45°46' N / 09°16'E, source height 50 m above ground) from which 100.000 particles were released continuously during the simulation intervals (from 2002/06/15 03:30 UTC to 2002/06/18 13:00 UTC). The model calculated u, v, w and turbulence, thus taking into account variances of wind velocity and Lagrangian autocorrelations. The spread of the particles was simulated with the Langevin equation.

Figure 4.21 displays the dispersion of polluted air from Milano over a period of three days. On June 17 the plume arrives at the location of the flight profile, i.e. Milano might have contributed. However, from the interpretation of the multiple tracer analyses an influence by biomass burning might be more likely than a contamination by urban or industrial provenance: In particular the relative low SF<sub>6</sub> mixing ratios and the delta<sup>13</sup>C value are indicating a rural source, and the CO data point to a fire in the smoldering stage (see figures 4.13. and 4.20.).

**Figure 4.21.**

Modelled dispersion of polluted air released continuously at the location of Milano (Italy).

The images are representing the positions of the particles on 16, 17 and 18 June 2002 at 4:30 UTC.

Profile site are indicated by the red star.

Modelling by GORKA PÉREZ-LANDA, CEAM

#### 4.2.3.3. Back Trajectory Calculations

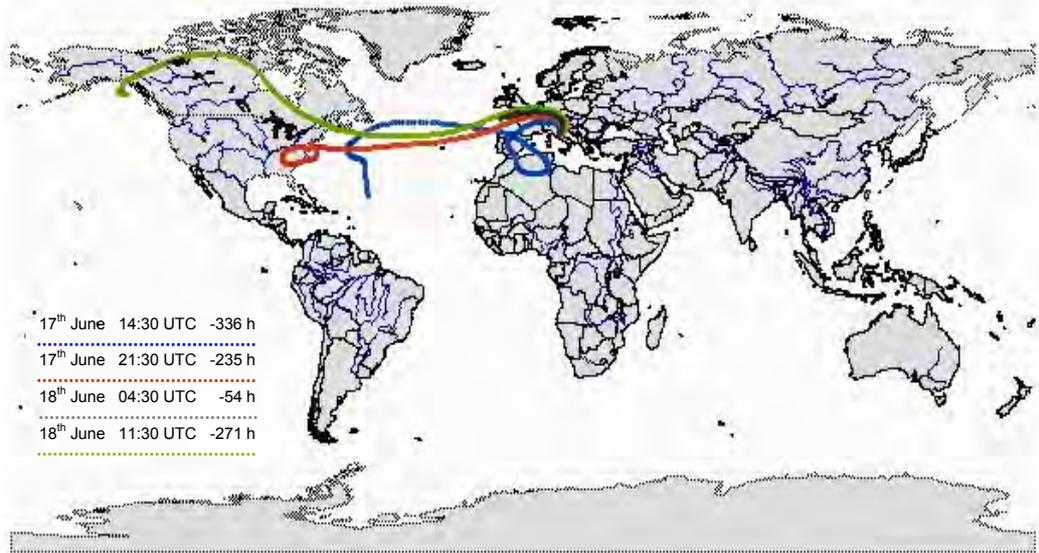

From the multiple tracer analyses as a source of the air sampled on 18 June 2002 at the 'Orvinio' site a wild fire event seems to be most probable. To narrow down suitable source areas back trajectories were calculated for the day before and the actual day the flask samples were taken.

The model revealed some interesting information: the occurrence of long range transport with a rapid crossing of the Atlantic Ocean is described by all model runs (see figures 4.22. and 4.23.) The backward calculation for a detection on 17 June 2002 at 14:30 UTC agrees with the pathways described by STOHL et al. [2003] for observations made in the context of the rapid transport of air masses by so called 'meteorological bomb' events.

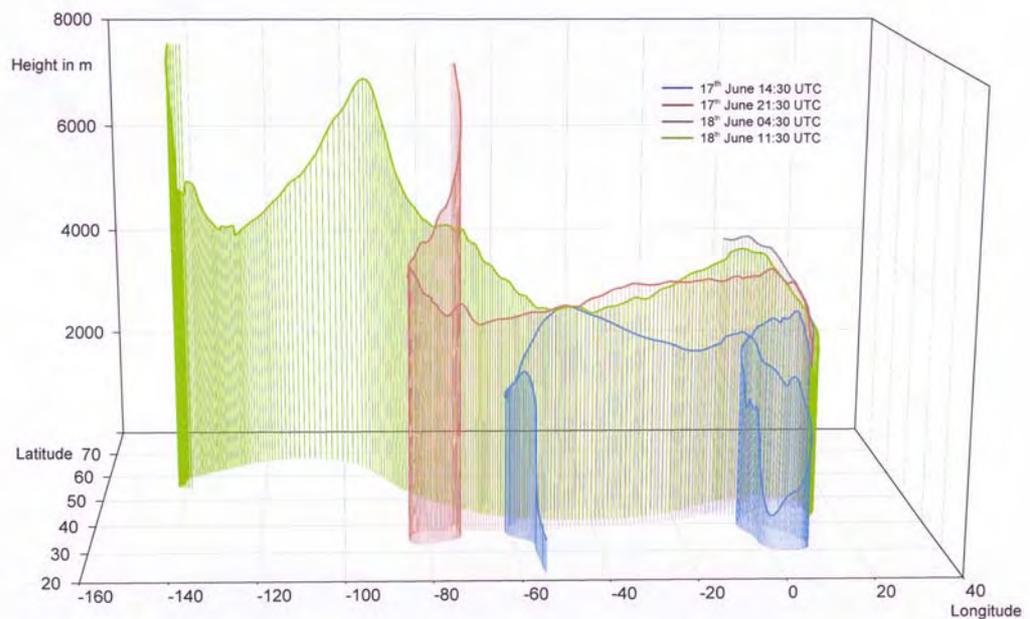

Since long range transport of air masses from North America to Europe have been described before [FORSTER et al. 2001] specific attention was given to this process. In a recent publication even the circulation of forest fire smoke around the entire globe is presented [DAMOAH et al. 2004]. The trajectories for June 17 (21:30 UTC) and 18 June 2002 (11:30 UTC) cross the Atlantic within the free troposphere.

From the MODIS fire observation database [<http://rapidfire.sci.gsfc.nasa.gov>] and the Web Fire Mapper Archive [<http://maps.geog.umd.edu/maps.asp>] wildfire events within the period and the spatial range of the 'particle pathways' could be identified on the east coast of the US as well as along the path in Canada (see the documentation of the 'Lazio Summer Campaign' on the CD-ROM).

Even if the time period between the assumed uptake of air from a smoke plume and the detection or sampling at the Italian mountain site comprises several days the origin of the sampled air from wild fires in the boreal areas of Canada and/or from the east coast of the US are most likely (see also figure 5.2.). Because of the clean air conditions at the heights the trajectories passed over the ocean one can assume that no major transformation happened on the way across the Atlantic (see figure 4.23.). This is reflected also by the composition of the air samples, which are indicating an origin from a remote site or the habitation during an extended time period without significant contact to anthropogenic activity (see figures 4.13. and 4.20.).

**Figure 4.22.** Back trajectories of air particles for a receiving point at the 2750 m sampling level above the Italian mountain study location 'Orvinio' (Lazio / Italy) using the 'HYPSPLIT' particle model [DRAXLER & HESS, 2002]. Assumed detections would be on 17 June at 14:30 and 21:30 UTC, 18 June at 11:30 UTC as also for the real sampling event at 04:30 UTC 18 June 2002. The total hours running backwards are indicated for each curve.

**Figure 4.23.** Same back trajectories as in figure 4.22. Displayed are the tracks and the heights.

Modelling by MARCUS SCHUMACHER, MPI-BGC

## Northern Europe

### 4.2.4. Uppland Summer Experiment 11 August – 9 September 2001

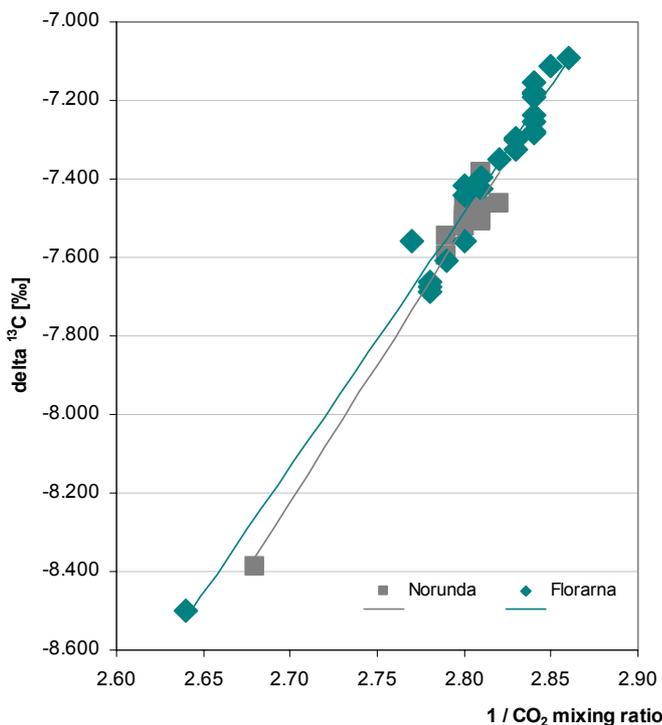

Even if the samples were taken two weeks after the investigations performed around the Norunda Tower, close to the end of the growing season, the data from the Florarna wetland site reflect higher diurnal amplitudes of the CO<sub>2</sub> mixing ratio. The plant activity can be clearly identified by the related isotope values, which are reflecting nearly perfectly the discrimination of the heavier <sup>13</sup>C isotope during assimilation (see data table in the documentation folder).

Another remarkable observation was the increase of the CO mixing ratios during day time. One possible explanation could be the conversion of CH<sub>4</sub> via formaldehyde to CO and H<sub>2</sub> (see reaction chain: 2.1.2.11 → 2.1.2.15a). However, because of the trend of the CH<sub>4</sub> mixing ratio (high night time values decreased until noon and then increased again in the afternoon) a CO production dominated by this formation seems unrealistic. A second process could be the conversion of VOCs, in particular since no indication of a source from traffic exhausts or biomass burning could be found via comparisons with the CO<sub>2</sub> mixing ratio or delta<sup>13</sup>C. Because a precursor of CO<sub>2</sub> is produced by the CO formation a more intense discussion of the observations will follow in chapter 5.2. (see figures 5.16 and 5.17).

Regarding all RECAP study regions the Uppland area provided the most homogeneous land use structure. Characteristics are the low rate of urbanisation and the absence of strong point sources, as found within the other campaign areas. Therefore only small disturbances by horizontal advection might be assumed. Nevertheless, the most likely explanation of the rapid CO increase at the Norunda site from midday to afternoon (see figure 4.4.) seems to be an exchange of the air mass by advection. But an identification of the origin is limited since high resolution wind field information is not available for the individual flight levels, nor were additional ground level reference samplings carried out for characteristic trace gas compositions and isotope ratios.

The intention of the sampling above two different typical land use units, the coniferous forest at Norunda and the Florarna wetland site, was to investigate the probability to detect the effects of individual sources and sinks.

A differentiation between the forest and the wetland location becomes clearly obvious from the  $\text{CO}_2$  /  $\delta^{13}\text{C}$  ratios (see figure 4.24.) and the  $\text{CH}_4$  mixing ratios. Because of the activity of methanogenic bacteria higher  $\text{CH}_4$  mixing ratios have to be expected in swampy areas, which were confirmed by the flask samplings (see figure 4.5.).

**Figure 4.24.**

Comparison of the *Norunda* site and the *Florarna* location (Uppland / Sweden) by the individual ratios of  $\delta^{13}\text{C}$  and the inverse  $\text{CO}_2$  mixing ratios.

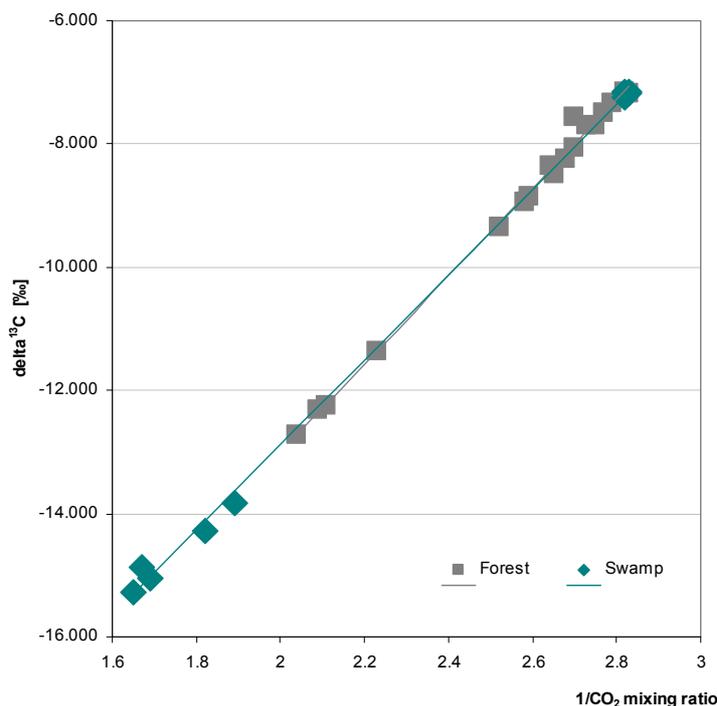

Norunda  $-27.2\text{‰}$ ,  $R^2 = 0.9667$   
 Florarna  $-25.6\text{‰}$ ,  $R^2 = 0.9691$

Flights performed at the *Norunda* site on 19 August, above the *Florarna* wetland on 29 and 30 August and 1 September 2001

With respect to the identification of individual contributions a closer examination was carried out at the Florarna site. At the ground level flask sampling was performed before sunrise and in the early afternoon to obtain distinct signals dominated by respiration and photosynthetic activity respectively, once within the open swamp and two times inside a wooded area. The afternoon sampling coincided with the flight activity, to get most actual data for the comparison of ground and flight samples and to minimize the potential of daily variations. Such variability was observed from the two investigations executed inside the wooded area (see also figure 4.25.). The differences seem to be mainly related to

temperature, humidity and in particular more stable conditions, caused by the reduced intensity of solar irradiance: during the cooler and rainy day higher CO<sub>2</sub> mixing ratios were recorded, correlated with more negative delta <sup>13</sup>C values, indicating that the respiration rate exceeded assimilation.

Regarding the comparison of both ground level locations in particular the fact that the data from the open swamp reflecting a higher uptake, even if the vegetation (mostly sedges) was already in an advanced stage of senescence, seems to be surprising. A hypothesis to explain this observation is that the samples taken within the open swamp might rather be reflecting a contribution from the surrounding forests. But only the night time samples could be clearly related to the vegetation unit of the individual location; CH<sub>4</sub> mixing ratios up to 6600 ppb over the swamp versus maxima ~ 1900 ppb inside the wooded area (see data table in the documentation folder) speak against it.

**Figure 4.25.**

Ratios of delta <sup>13</sup>C and inverses CO<sub>2</sub> mixing ratios from the ground level investigations at the *Florama* site (Uppland / Sweden) inside the wooded area and within the open swamp area.

The differing sources of CO<sub>2</sub> are indicated by the slightly different linear regression intercepts.

Forest -27.3‰, R<sup>2</sup> = 0.9956  
 Swamp -26.7‰, R<sup>2</sup> = 0.9989

However, since during day time higher wind velocities were recorded than during the night horizontal transport which affected the day time samplings could not be excluded. Also when taking the other trace gases into account no clear differentiation between the wooded part and the open swamp is possible.

Despite the large uncertainty an interpretation of the different values for both sites is attempted. Regarding the relation of inverse CO<sub>2</sub> and delta<sup>13</sup>C the wetland samples seemed to be affected by different sources than the ones from the wooded part, which are characterised by slightly more negative delta<sup>13</sup>C (see figure 4.25). This relation is nearly equal to the one obtained from the flights above the forest around the Norunda tower. However, the expected mixed signal from wetland and forest was not reflected by the Florarna flight samplings; instead a source characterised by a less negative value seemed to be dominant (see also figure 4.24.), which could not be identified from the available observations.

From the comparison of the ground and the flight data two conclusions can be obtained: (1) although the lowest flight level was at 50 m above ground (30 – 40 m above the canopy) the morning flights did not sample the boundary layer. (2) The measurements are affected by advection even in this rather homogeneous terrain.

## Central Europe

### 4.2.5. Thuringia Summer Experiment

15 July – 2 August 2001

When comparing the results from both locations in particular the higher mixing ratios at the 'Gebesee' site became obvious. Especially the morning sample taken at the lowest level is surprising, since for two reasons a smaller difference to the data from the 'Hainich' should be expected: Because most of the crops in the surrounding area of Gebesee were just in the stage of maturity a weaker signal reflecting plant activity might be assumed. And, since the sampling at the 'Hainich' was performed nearly one and a half hours earlier the contribution from respiration should be more distinct at that site. A probable explanation could be that at the 'Gebesee' site an air plume of urban origin was sampled, released with the starting thermal mixing from the stable nighttime boundary layer. In addition a further contribution by horizontal transport might be possible. Advection seems in general not negligible since related variations were observed by the diurnal samplings also for the other trace gases. Similar conclusions may be drawn from the 'Hainich' flights. For the rather small decrease of CO<sub>2</sub> mixing ratios between midday and afternoon the vegetation seems not to be responsible, since no signs related to a reduction of the photosynthetic activity were observed. The comparison of the gas and isotope ratios indicates that the variability might be rather a result from advection, masking the photosynthetic activity by the replacement of the rural local air by air of more urban origin.

Because of the unknown degree of disturbances the flask samples did not allow a budgeting.

#### 4.2.6 The Netherlands Winter Experiment      14 January – 10 February 2002

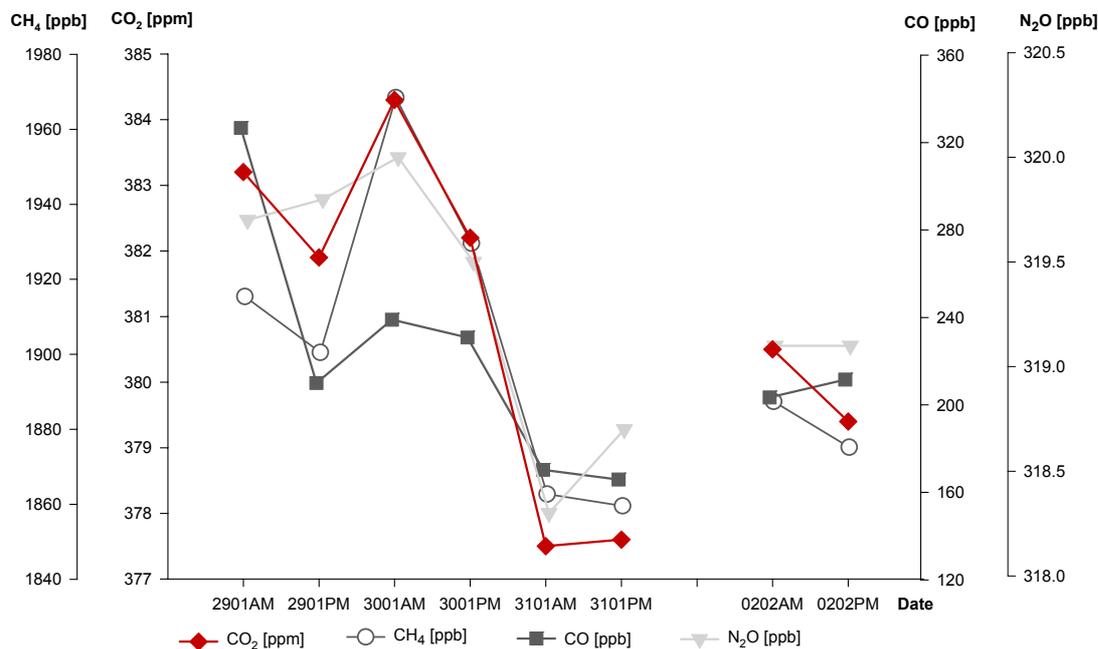

The observed development of the CO<sub>2</sub> mixing ratio and the delta <sup>13</sup>C values during day time, as already presented in figure 4.11, point to a contribution by plant activity although such an effect of the vegetation seems not to be realistic in winter. Data obtained from ground level and from the profile flights over marshland reflect a tendency, which can not be explained by the activity of the sparse grass cover. More likely is that the area was affected by urban influences. This can be seen from the CO<sub>2</sub>, the delta<sup>13</sup>C and the CO data of the samples taken at 5 m height in the morning which are indicating products related to combustion processes. Since the sampling was performed a few hundred meters away from any settlements, advection must be an important parameter regarding the transport of contaminations from sources located upwind.

The relevance of advection as a major interfering parameter becomes also obvious from the shape of the flight profile. Lower mixing ratios of CO<sub>2</sub> and CO, as well as a reduced amount of the <sup>13</sup>C isotope were sampled in the free troposphere, compared to the ones taken within the CBL. Additionally a decrease can be recognized between the morning and the midday samples, which becomes particularly distinct for the CO mixing ratio. The most probable explanation is air exchange, whereby air of marine origin became more dominant.

When comparing the data from all flight days a high variability is recognizable also from day-to-day (see figure 4.26). By correlating the different tracers a rough differentiation of the origin of the sampled air masses might be possible, whereby the clearest signal for air with an oceanic character can be seen in the data from the morning flight on the 3<sup>rd</sup> January.

Because of the observed day-to-day variability the determination of a background value from the samples taken within the free troposphere was impossible.

‘Contaminations’ caused by air mass changes might frequently not be identified.

**Figure 4.26.** Mixing ratios of CH<sub>4</sub>, CO<sub>2</sub>, CO and N<sub>2</sub>O obtained from the flask samples executed on the 29, 30, 31 January and the 2 February 2002 above the *Forest* site at lowest flight level (The Netherlands).

Additionally, due to the highly variable wind conditions each profile has its own characteristics. The results from the flights over the same area cannot be classified. And since wind direction was never really stable during a complete flight day, the ‘transect approach’ could not be defined either.

Regarding the technical improvements, which were realized since the previous campaigns concerning flask pair differences, no systematic tendency, indicating a further influence of the [Mg(ClO<sub>4</sub>)<sub>2</sub>], could be observed anymore. The remaining differences are in the range of the expected and observed small scale variability.

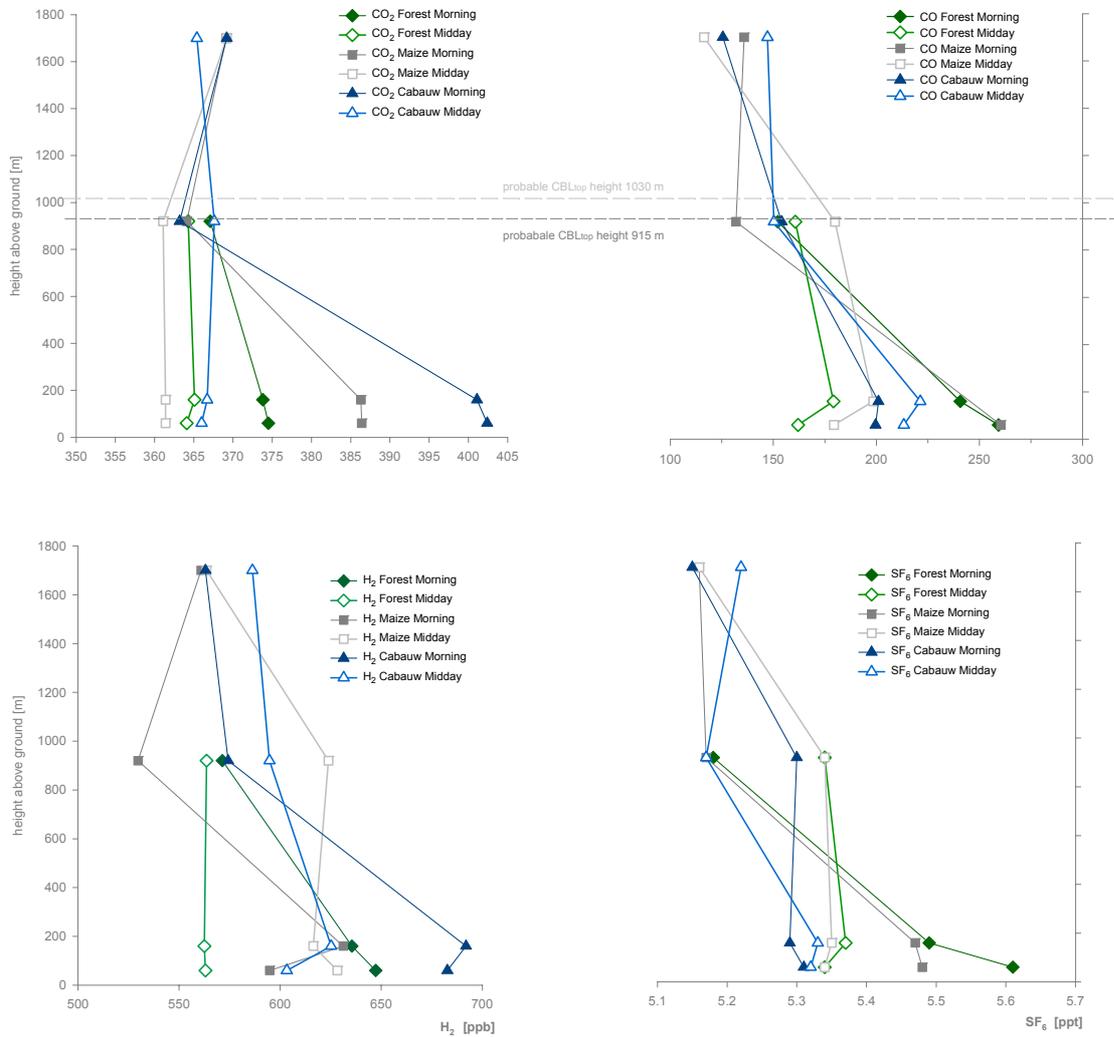

When comparing the results obtained from the flight profiles and the ground reference investigations, shown in figures 4.15. and 4.16., a discrepancy between both locations and between the ground and the flight samples taken at the individual sites becomes obvious. Contrary to the clear signals related to the plant activity identified by the ground samples, only a small signal can be detected in the flight results. Regarding the Cabauw data one explanation might be the late hour of the morning sampling: a contribution of air from the residual layer of the previous day might be entrained by vertical mixing. And the CO<sub>2</sub> uptake during assimilation should be already effective. In this case one has to expect significantly decreased CO<sub>2</sub> mixing ratios around noon, since the photosynthetic activity and turbulent mixing processes are assumed to be most effective during the middle of the day. Since such a clear signal was not found it is likely that the signals obtained from the flight profile are masked by an air mass change between the morning and the midday samplings, which could be confirmed also by the variations of the CO mixing ratios. In this context the data of the samples taken at the 915 m level above the 'Maize' location must be interpreted as the signal of an isolated layer with a distinctly different origin.

The large differences between both sites, which became obvious from the ground reference samples, are reflecting clearly the different local land use characters. In particular, the relative high CO ratios obtained from the marshland samples might mirror more pronounced anthropogenic influences (close distance to major agglomerations) than for the maize field.

#### *Sampling approach*

An important question resulting from the local observations was to identify the sites and sampling heights which are characteristic for the entire region to be described. In theory the regional carbon budget should be estimated by a) the summation of the individual contributors or b) the measurement of an air column containing a well mixed average of them. Consequently the analysis of the entire air column of the flight profile should lead to the identical result as the one got from the

estimation obtained from the spatially weighted contributions of the local sources and sinks.

**Figure 4.27.** Summary of the CO<sub>2</sub>, CO, H<sub>2</sub> and SF<sub>6</sub> gas mixing ratios obtained from the profile samplings performed on 27 July 2002 above the three different study sites (The Netherlands).

In particular differences among the sub-regional territories became obvious for the morning flights by the comparison of the individual profile sites (see figure 4.27). From the signatures of the lower level samples the main land classes could be well differentiated, as well as a continuous homogenization with increasing height was observed. But at no altitude a blending height was identified, that could be labelled as 'representative' for the entire region. Thus the question has to be answered

how important is the selection of the individual profile site is with respect to the budget of a larger area.

To substantiate these conclusions the results from the 27 July 2002 may be taken for example. In order to obtain the regional surface fluxes from the observed diurnal mixing ratio differences in the CBL profile, the fluxes for the individual profile sites were calculated with a simple budget equation:

$$F_{\text{CO}_2} = \frac{d(\text{CO}_2)_m}{dx} \frac{dx}{dt} \rho_m h \quad [4.1.]$$

$F_{\text{CO}_2}$  is the flux density at the surface, expressed as micromoles per square meter per second. By inserting  $h$  (the height of the CBL top) combined with a mean wind velocity  $\bar{u} = 2.4 \text{ m s}^{-1}$  to obtain  $dx / dt$ , the spatial extension of the study region is defined.  $\rho_m$  is the mean molar density of the air.

Exemplary surface fluxes and the regional extensions for the three different study sites were calculated for two CBL top heights:

**Table 4.11. Estimated CO<sub>2</sub> surface fluxes calculated for two different CBL top heights on 27 July 2002 at the field sites in The Netherlands**

Site	CBL <sub>top</sub> height = 1030 m	CBL <sub>top</sub> height = 915 m
	flux (μmol / m <sup>2</sup> s)	flux (μmol / m <sup>2</sup> s)
Forest	-7.08	-6.53
Maize	-11.16	-10.29
Cabauw	-23.82	-22.36

The advection distances between the morning and afternoon flights were 51.8 km (CBL<sub>top</sub> height = 1030 m) and 48.5 km (CBL<sub>top</sub> height = 915 m), respectively.

For comparison: the fluxes measured by eddy-correlation on 27 July 2002 at the Cabauw Tower were -9.7 μmol / m<sup>2</sup> s in the morning and -10.4 μmol / m<sup>2</sup> s around noon.

Since the determination of the CBL top height from the measured and derived gradients of humidity  $f$  and potential temperature  $\theta$  is difficult, one has to take into account that an uncertainty with respect to the quality of the calculated fluxes exists.

For instance the range of the top heights obtained and used by the different groups in RECAP for 27 July 2002 varied between 955 m and 1500 m.

When comparing the data, in particular the absolute values observed at the Forest and at the Cabauw site, some results are significantly different from the expected ones. The calculated flux at Cabauw seems to be unrealistically high, whereas the Forest value appears to be too low.

The question arises: *what* affects the observed 'fluxes'? Can the fluxes be attributed to surface processes or are they mainly caused by variations of the air mass origin. Both cases are seriously affecting the budgeting process and the investigation strategy.

Two explanations seem most probable.

(1) The local conditions are represented to a larger extent than assumed so far. If the local ground conditions are dominating the composition of the entire profile, the selection of the sampling site would have the most crucial importance for the investigation, since the ground has to be representative for the whole region.

(2) Changing environmental conditions, resulting in air mass changes, is a key factor. If air mass changes are predominant, affecting smaller scales than covered by the spatial range of the individual profile sites, the sample sites can no longer be directly compared, because of the different background shifts.

Regarding this conclusion of dominating environmental conditions, confirmed by the high variability of wind velocity and direction, the CBL budgeting approach is impossible.

Disturbances, caused by wind direction variability, are the main restriction for the application of the 'transect approach'. Even if the stretch of the study sites was orientated along the main wind direction, individual short term changes of wind direction occurred at the different sampling levels. Therefore changing by lateral advection affected the samples at the different sites. Thus each profile, respectively each sample level, appears to be completely independent and will not

be representative for the regional air mass. Caused by the insufficient knowledge of the environmental conditions, like advection, CBL height, etc. no direct regional budget estimation is possible with profiles measured above a single site.

However, in spite of all difficulties, some results could be obtained regarding the comparison of the winter and the summer investigations. The elevated CO<sub>2</sub> and CO mixing ratios observed within the free troposphere are reflecting the higher contribution of fossil fuel consumption in winter. Also from the lower level samples a differentiation of diverse sources and sinks between summer and winter flights became obvious. Caused by the high night time respiration of the vegetation, no significant difference could be observed during the morning hours in summer, in contrast to the afternoon samples which are characterised by a clear reduction of CO<sub>2</sub> mixing ratios caused by plant activity.

#### **4.2.8.1. SPA<sup>13</sup>C Thuringia Summer Experiment 6 – 15 August 2002**

Because of the opportunity to verify all improvements and adaptations in combination with high precision ground level investigations the SPA<sup>13</sup>C experiment was highly suitable regarding a final assessment of the methodology. Additional information could also be obtained from cooperation with the modelling department of the MPI-BGC (CHRISTIAN RÖDENBECK).

From the profiles of figure 4.17 a good agreement of the data obtained by the tower sampling and the sampling performed with the flight unit becomes obvious, i.e. there was no affection due to the different technical equipment and no discrepancy regarding the observed spatial scales. With respect to the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values both reflected the expected diurnal tendencies and amounts. A remarkable observation from the tower sampling is the occurrence of significantly higher CO<sub>2</sub> mixing ratios correlated with more negative delta<sup>13</sup>C values beneath the beech canopy from the samples taken around midday, which indicates both a high assimilation activity and contribution also from soil respiration. On the other hand the CO<sub>2</sub> decrease and the relative increase of the <sup>13</sup>C isotope within and above the canopy reflect a change from predominating respiration to a sink by CO<sub>2</sub> uptake. In particular for the midday observation the influence of local sources, the soil respiration, and of local sinks, the canopy, becomes obvious.

The combination multi tracer flask samples and continuous profiles allowed the further investigation of the sampling strategy and the budgeting approach: the effects of advection for diurnal and day-to-day time scales and the occurrence of stable stratification.

##### *DAY-TO DAY VARIABILITY*

A clear differentiation could be made between both days by the analysis and interpretation of the air samplings. 14 August 2002 was characterised by averaged gas mixing ratios close to the global mean values, which suggests, that the air mass was less affected by terrestrial sources but rather likely of maritime origin. Contrary to these results the data of 15 August 2002 show a conspicuous increase of all trace gas mixing ratios, wherefrom an increasing influence of

anthropogenic sources can be derived. The variation of the CO mixing ratios exceeds with more than 30 % from day-to-day even the relatively high diurnal variation by a factor ten. Suggested by the CO<sub>2</sub> and delta<sup>13</sup>C ratio (see figure 4.9) a contribution of biological, respectively plant activity can be identified. Thus the air mass sampled on 15 August is of terrestrial origin.

	14.08.	15.08.

**Table 4.12.** Summary of the means from the entire profile for CO<sub>2</sub>, CO, H<sub>2</sub> and SF<sub>6</sub> gas mixing ratios sampled on 14 and 15 August 2002 above the *Hainich* (Thuringia / Germany). The variability in between the days expressed in percent is related to the relative mixing ratio change of the samples from 15 August (terrestrial) to the sampling at the same time the day before (marine character). Likewise the differences are calculated between the results of the midday flight on 14 and the morning flight on 15 August.

To assess the effect of an air mass change on surface flux estimates specific calculations were carried out with equation 4.1 for CO<sub>2</sub> and for hypothetical fluxes of CO, H<sub>2</sub> and SF<sub>6</sub> [SF<sub>6</sub> has no terrestrial sinks!].

**Table 4.13.** Calculated fluxes for CO<sub>2</sub> and CO, H<sub>2</sub> and SF<sub>6</sub> from the flight data of 14 and 15 August 2002 above the *Hainich* (Thuringia / Germany) using equation 4.1.

14.08.	15.08.	14.08.	15.08.	14.08.	15.08.	14.08.	15.08.
-20.0	-16.2	-14.6	-15.2	2.2	-24.4	-0.05	-0.32
CO <sub>2</sub> [μmol / m <sup>2</sup> s]		CO [nmol / m <sup>2</sup> s]		H <sub>2</sub> [nmol / m <sup>2</sup> s]		SF <sub>6</sub> [pmol / m <sup>2</sup> s]	

On 14 and 15 August 2002 'fluxes' with negative notations (excluding H<sub>2</sub> on August 14 2002) can be recognized, whereby for all gases except CO<sub>2</sub> a higher

decrease is indicated on 15 August 2002. This observation might be in conflict with the carbon budgeting: In particular air mass change is indicated by

- 1) the observed increase of  $H_2$  and the nearly steady mixing ratio of  $SF_6$  in the afternoon on 14 August 2002, and by the
- 2) decrease between the morning and the midday sampling on 15 August 2002.

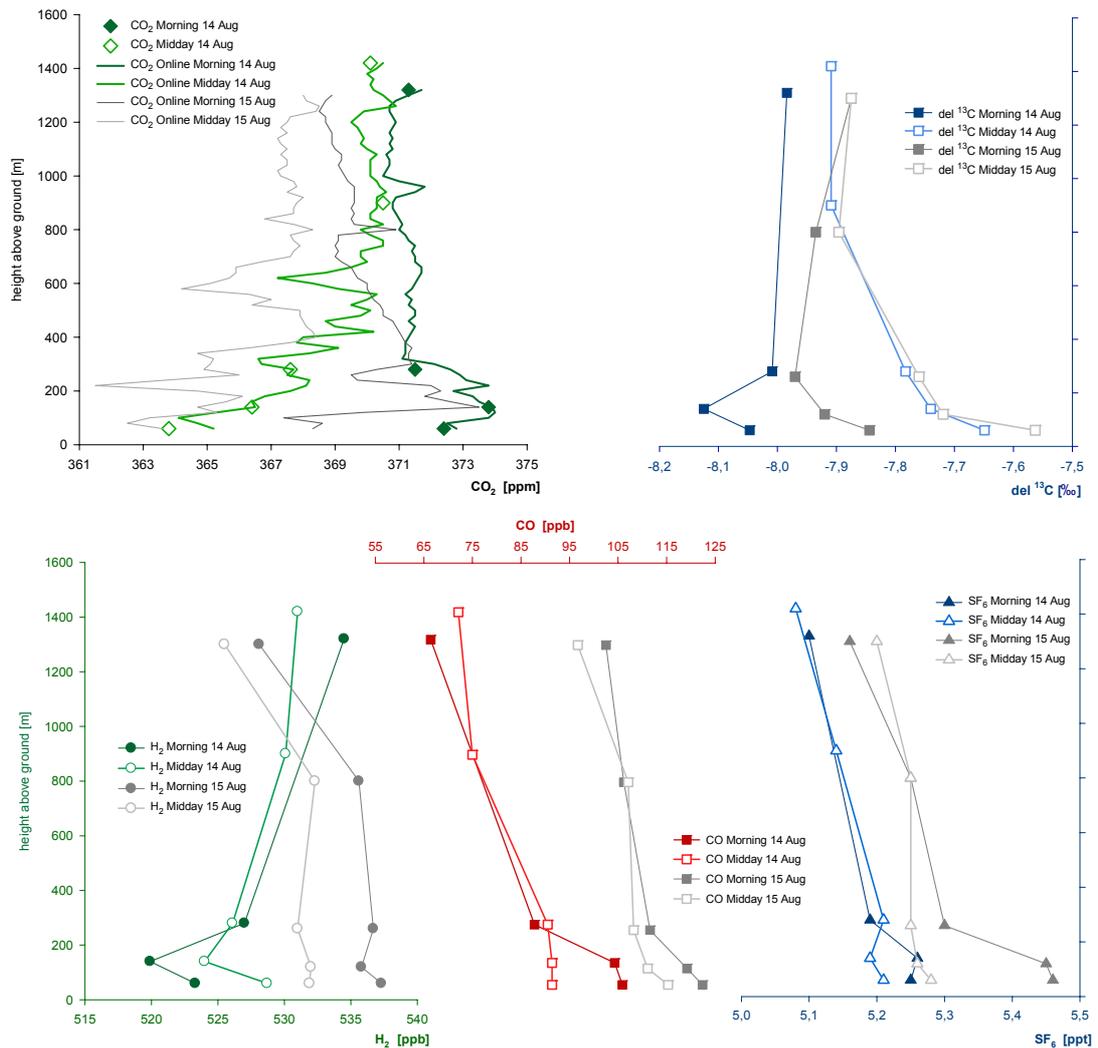

With respect to the carbon budgeting it has to be assumed, that the origin - and thus the mixing ratio - of the sampled  $CO_2$  also have changed. Thus an unknown fraction of the 'calculated' fluxes might come from outside the region.

Specific studies were initiated in order to get additional information about the exchange processes caused by the day-to-day variability and to verify the origin of the air masses with a transport model (see sub chapter 4.2.8.2; 'Adjoint of a Transport Model'). More specific multiple tracer analyses are also presented in chapter 5.2. 'Variability – Air Mass Change'.

#### *STRATIFIED LAYERS*

Following theory stratified layers shall be coupled to stable thermodynamic conditions and should therefore normally be expected in the early morning hours, during winter or at the CBL top. Also during midday flights on both days the presence of isolated layers within the profiles was documented by the continuous  $CO_2$  measurements (see figure 4.28). Discontinuities of the mixing ratio occurred, for example during the midday flight on 15 August within the small height range between 170 and 270 m; from 366.1 ppm to 361.5 ppm and up again to 366.4 ppm. Relating this small scale vertical variability to the variation of the diurnal cycle of  $CO_2$ , which is  $\sim 3$  ppm, a high uncertainty regarding the representativeness of the individual flask samples becomes obvious.

Differences between the online  $CO_2$  measurements and the results from the flask sampling can be recognized in particular at the lowest flight level, due to the identified small scale variability. This direct comparison of the data from both systems became possible with the modifications of the sample system by the implementation of the coupled record documentation (see chapter 3.4 , table 3.6).

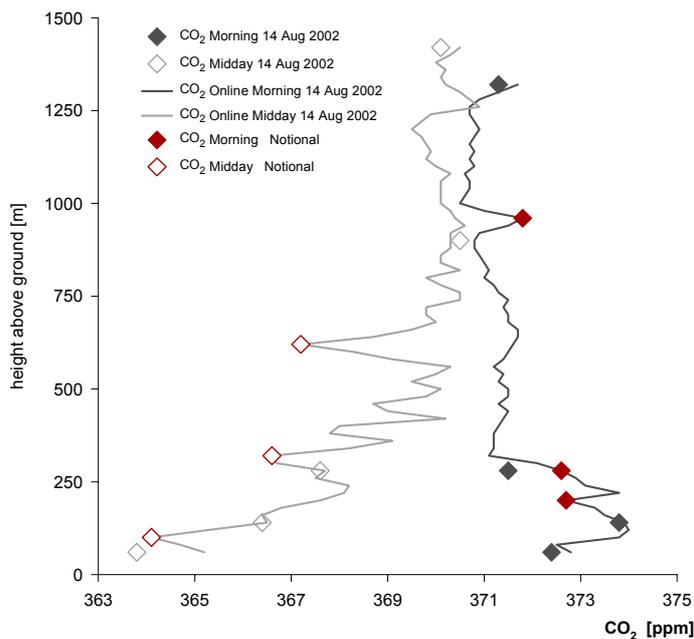

**Figure 4.28.** Mixing ratios of CO<sub>2</sub>, CO, H<sub>2</sub>, SF<sub>6</sub> and delta<sup>13</sup>C in CO<sub>2</sub> from the samples above the *Hainich* (Thuringia / Germany) on 14 and 15 August 2002. The CO<sub>2</sub> plot also contains the mixing ratio profiles obtained by the continuous system. Although small scale variability differences between the online results and the flask data can be expected (in particular near to the ground) an acceptable agreement could be achieved by the improved sampling system.

The online system adds valuable information regarding the CO<sub>2</sub> profile that allows to identify of stratified layers and the description of the direct environmental conditions when taking the air samples.

From the occurrence of stratification uncertainties arises, which are not only crucial for discrete sampling approaches. Regarding the significance for flask sampling two aspects could be separated: 1) depending on the level the samples are taken the difference in the mixing ratios between both flights might change significantly.

2) If the layers are characterised by different source areas and formation processes random biases regarding the signal interpretation may be provoked (see for instance chapter 5.2. 'Signal shift').

Figure 4.29 presents the profile data from the flights performed on 14 August 2002. Indicated by the red symbols are notional samples 'taken' at different levels adapted to the continuous CO<sub>2</sub> profile records. When calculating CO<sub>2</sub> fluxes for both cases, the real and the assumed flask sampling, large discrepancies appear. The notional CO<sub>2</sub> morning mixing ratios are 0.3 ppm higher, at midday 1.6 ppm lower compared with the real sampled data. This results in an assumed CO<sub>2</sub> flux of  $-23.29 \mu\text{mol m}^{-2} \text{s}^{-1}$  versus  $-12.99 \mu\text{mol m}^{-2} \text{s}^{-1}$  calculated from the real flask data – which is only 55% of the hypothetical amount.

**Figure 4.29.**

CO<sub>2</sub> mixing ratios recorded by the online system (greyish lines) and obtained from flask sampling (greyish symbols) on 14 August 2002 during the flights over the Hainich (Germany). Red symbols are hypothetical samples 'taken' at different levels adapted to the continuous records, used for the estimation of the error potential regarding flask sampling in stratified air masses.

If the layers are caused by diverse source areas and formation processes, and transported to the profile site by advection, each of them has to be taken as an independent contribution, which even might be in no way associated with the regional surface flux. Therefore, also from a continuously profile surface fluxes cannot be derived.

With respect to the characterisation of the individual layers multiple tracer analyses will be a useful tool. However, for the required in-flight detection of the layers the

implementation of further continuous systems, at least of an additional CO sensor, is mandatory.

#### *INTERACTIONS CAUSED BY TOPOGRAPHY*

Because of the simultaneous observation of horizontal advection and the presence of stratified layers a further aspect might have to be taken into account.

The Hainich location is characterised by a steep slope to the Werra valley in the west (200 m level difference), the barrier of Harz Mountains (Brocken 1142 m) and Thüringer Wald (Großer Finsterberg 944 m) north and respectively south of the Hainich. It can be assumed that due to the orographical situation an aerodynamic, undulated pattern is initiated. By the establishment of this stationary wavelike structure an attenuation of convective processes at the troughs can be assumed. One consequence might be the conservation of stratification. Additionally, the establishment of an irregular 3 dimensional flow field may partially explain the occurrence of the frequent small scale variability and the differences between the tower and flight measurements during the first flights over the Hainich (see chapter 3.1.3.) and the transect flights described by GIOLI et al. [2004].

#### 4.2.8.2. Inverse Study

Because of the wide range of the observed mixing ratios even nationwide influences seems to be quite probable. Our intention was to verify the assumption of a crucial contribution by advection and to get an estimate of the disturbance.

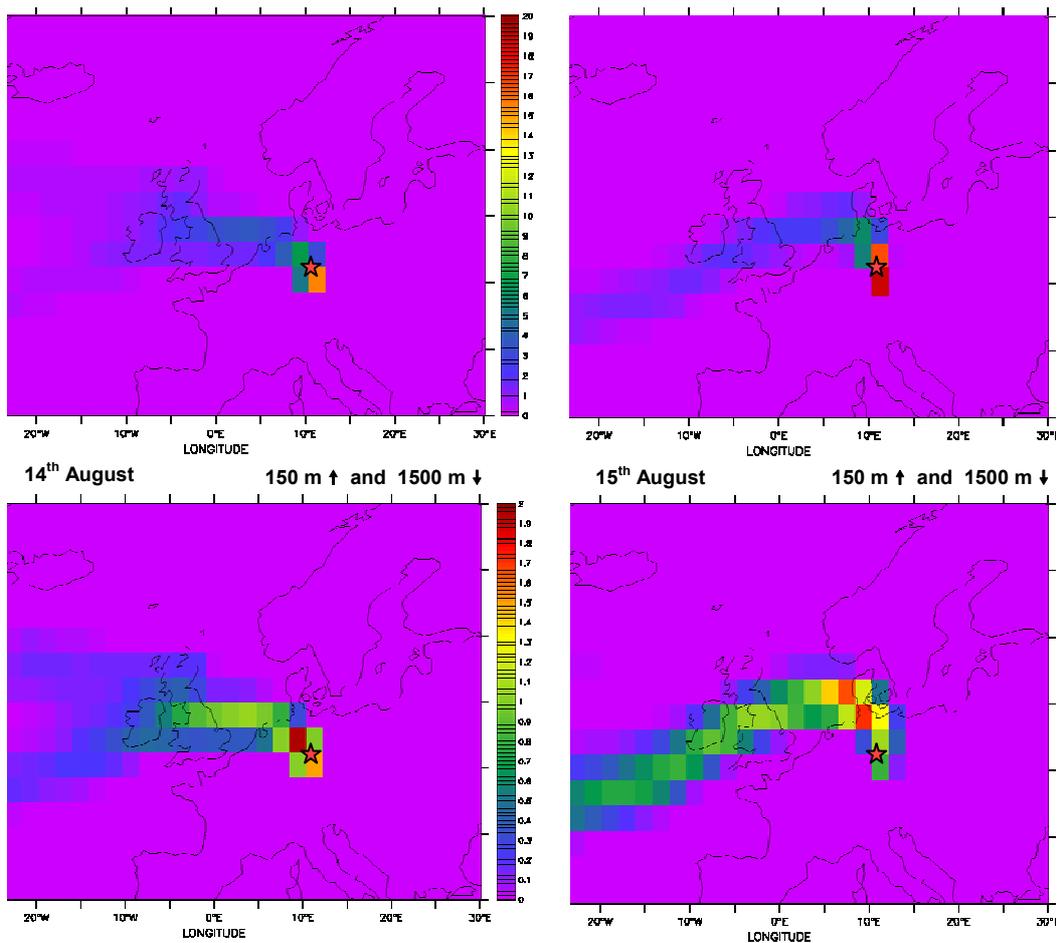

##### Adjoint of a Transport Model

To evaluate the observed different gas compositions spatial contribution probabilities were calculated by an adjoint of the TM3 global 3D atmospheric tracer transport model, supported by CHRISTIAN RÖDENBECK from the MPI-BGC.

Calculated were the individual grid box contributions to the CO<sub>2</sub> mixing ratio increase (indicated in ppm), that would be observed corresponding to an assumed tracer flux of 10<sup>6</sup> mol s<sup>-1</sup> (see figure 4.30.) For an estimate of the amount that is directly related to anthropogenic interferences the investigation was combined with data base information of CO<sub>2</sub> emissions from fossil fuel consumption. Therefore the sensitivities were weighted with the spatial distribution of the fossil fuel emissions, obtained from the EDGAR data base. The plots are showing the contribution in ppm of the individual grid boxes, which would be recognized at the observation site (see figure 4.31).

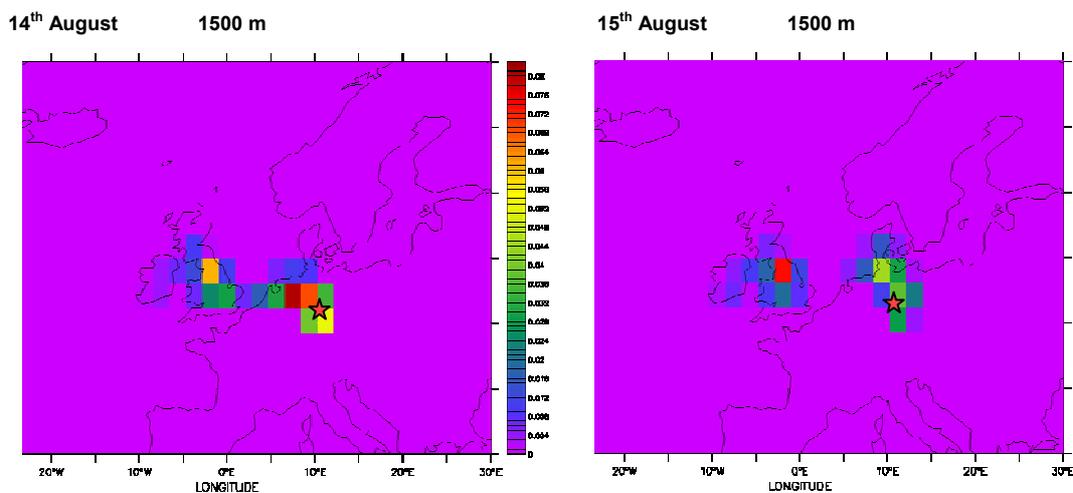

The proposition, that the air mass measured on 15 August 2002 is of a different, more terrestrial origin, seems to be proven, since the transport function identifies also a relative high number of terrestrial cells with high potential to contribute to the measured results. A high input from the grid box located at the central UK industrial region might agree well with the observed rapid change of the gas mixing ratios (see table 4.12 and figure 4.28). On the other hand the model does not reflect the direct surroundings of the profile site properly regarding the sampling level above the CBL top. Because the resolution of the vertical structure is relatively coarse in the model, a capping inversion will not be taken accurately into account. This may explain the overestimation of the boxes which are connected directly to the measurement point.

However, regarding an estimation of the contributions from remote sources by long range transport the model provides helpful information. On the other hand the results from the gas and the isotope analyses and their interpretation can provide probable information with respect to model evaluations.

**Figure 4.29.** Contributed mixing ratio increases which would be measured corresponding to the assumed tracer flux at each grid box. The calculations are related to the sampling flights at 10:45 UTC on 14 and 15 August 2002.

Modelling by CHRISTIAN RÖDENBECK, MPI-BGC

**Figure 4.30.** Individual contribution of each grid cell with respect to the fossil fuel emissions as estimated from the EDGAR inventory to the mixing ratio at the profile location. (Site is indicated by the red star) Modelling by CHRISTIAN RÖDENBECK, MPI-BGC

## 5. DISCUSSION

Objective of this chapter is a more thorough discussion of the results obtained from multiple tracer analyses and their potential for carbon budgets.

It is structured into four parts, focussing on specific subjects: 1) characterisation and comparison of the RECAB study regions by multiple tracer analyses, 2) examination of theoretical and conceptual aspects, 3) summary of the methodological experiences, and 4) the benefits derived by the establishment of the ground reference sampling unit and – as the resulting consequence of the findings - the enhanced understanding from the sophisticated flight investigation strategy.

The field campaign results will be interpreted and discussed first for each study region individually. Then exemplified findings, concerning specific topics with respect to the budgeting, will be presented in more detail. Then some general effects regarding theoretical and conceptual aspects will be discussed, leading to a conclusion with respect to the applicability of the CBL-budget approach for studies bases on flask sampling. Before the enhanced investigation strategy will be scrutinized, the most important impairments regarding the practicability of airborne CBL studies are concisely presented.

For the development of the sampling unit several experiments were carried out in the laboratory, during test flights and RECAB campaigns. Cross references will be given with respect to the observations which initiated the laboratory experiments, and to the perceptions derived from the flights. A summary of the modifications and an assessment of the improvements was already given in chapter 3.4 (pages 56 ff.), directly connected to the discussion of the related laboratory experiments.

Also the adaptations of the flight and sampling strategy were motivated by campaign observations. Linkages between causes and effects are pointed out.

## 5.1. Comparison of the Study Regions using Multiple Tracer Data

Emphasis of this section is to discuss the results of the RECAP field campaigns presented in chapters 4.1. and 4.2. by using multiple tracer analyses and to evaluate the potential of multiple tracer studies using real field data. The first part of the section discusses the potential with respect to specific processes.

With the integration of CO, SF<sub>6</sub> and H<sub>2</sub> into the analysis scheme three additional trace gases with distinct different characteristics became available (since the campaign in Sweden in 2001). CO and H<sub>2</sub> should be used as tracers for CO<sub>2</sub> that originated from combustion processes, whereas SF<sub>6</sub> was related to the identification of urban, in particular of industrial contributions.

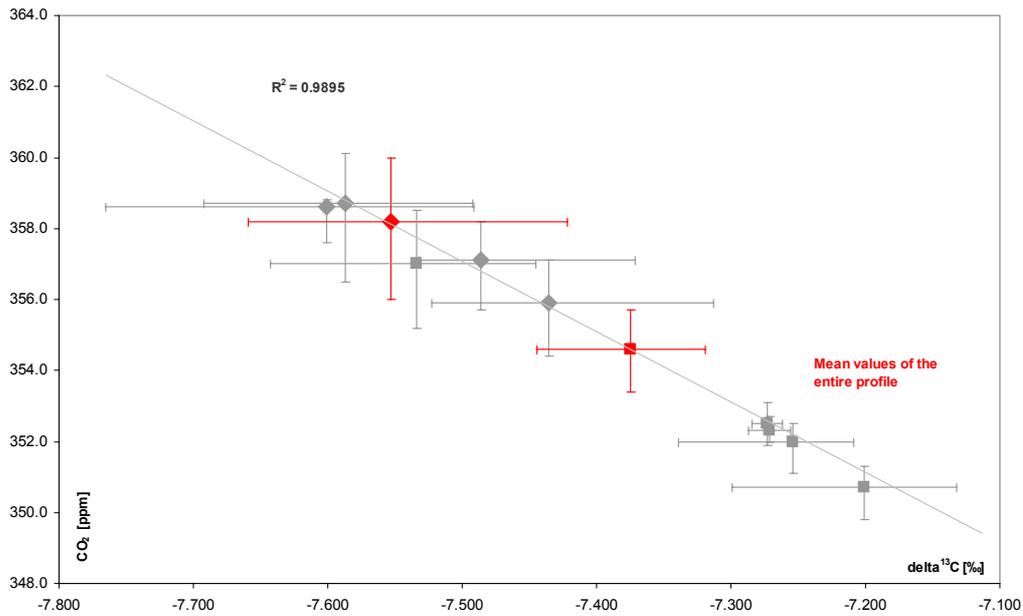

By the interpretation of the multiple tracer data some of the affecting processes could be compiled. However, a general problem of flask sampling analyses becomes also obvious: uncertainties due to the low amount of data.

### 5.1.1. CO<sub>2</sub> / delta<sup>13</sup>C and CO<sub>2</sub> / CO relationships

#### *CARBON DIOXIDE AND ISOTOPIC SIGNATURE*

Individual sources and sinks, like for example plants, are characterised by a specific CO<sub>2</sub> / delta<sup>13</sup>C relationship, where the signal caused by the <sup>13</sup>C discrimination during the assimilation activity has its pendant in the value obtained from the respired air. When analysing air samples: The more uniform and the larger the sources and sinks are, the clearer is the observable signal. Thus a high correlation coefficient will reflect a mostly homogeneous area, whereas variable contributions from different sources might cause a weak relationship (see figure 5.1).

An important factor is the concurrent seasonality of determining processes. During summer low CO<sub>2</sub> mixing ratios and less negative delta<sup>13</sup>C values can be observed, because of high assimilation activity and low contributions from fossil fuel consumption (in particular from heating). Contrary conditions occur in winter time (see figures 5.3 and 5.16).

**Figure 5.1.** CO<sub>2</sub> / delta <sup>13</sup>C ratios obtained from the samples collected over *Florarna* on 29 and 30 August and on 1 September 2001 (Uppland / Sweden). A linear fit through the data points is applied. The range of the mixing ratio during all days is indicated by the bars for CO<sub>2</sub> and delta <sup>13</sup>C respectively. Morning flight data are plotted as diamonds, the midday results as solid squares. Because of the delayed morning sampling on 1 September the obtained lowest level variances are not directly comparable. The 60 m morning data were therefore excluded. (likewise in figure 5.16)

Likewise the released CO<sub>2</sub> from fossil fuel consumption is characterised by distinct CO<sub>2</sub> / delta <sup>13</sup>C ratios depending on fuel types (see table 5.1).

At least a differentiation of the diverse RECAP study regions should be derivable. Results from CO<sub>2</sub> / delta <sup>13</sup>C correlation analyses are more specifically discussed under seasonal and latitudinal aspects in subsection 5.1.2.1.

**Table 5.1.** delta <sup>13</sup>C signature of different carbon sources

<b>Light Methane</b> (from methanogenic sources)	- 110.0		HOEFS 1996

COMBUSTION PROCESSES

Besides the information obtained from the correlation of CO<sub>2</sub> and the isotopic ratio additional information is contained in the relationship between CO<sub>2</sub> and CO especially on combustion processes. Since the ratios of CO<sub>2</sub> and CO released from combustion processes are depending mainly on fire temperature, material and the kind of burning a differentiation of individual sources is possible. In smoldering stages, which is often a characteristic of biomass burning, CO release is significantly increased compared to a combustion with an open flame (see chapter 2.1.2.2. 'Carbon Monoxide'). If the source processes could be identified a first estimation of the added CO<sub>2</sub> can be achieved. With respect to the identification of contributions from fossil fuel consumption the additional implementation of <sup>14</sup>C into the analyses scheme would be desirable.

From the agricultural (named 'Maize') site in The Netherlands CO<sub>2</sub> and CO data are available from the winter and the summer campaign (see table 5.2). Most obvious is that in particular the CO<sub>2</sub> and CO mixing ratios of the midday samplings (indicated in red colour) vary much between summer and winter time. The variability of the mixing ratios between the days of the individual campaigns is much higher for CO than for CO<sub>2</sub>; but the range of the CO mixing ratio is even highest in summer time. This might be an effect of different seasonal synoptic conditions.

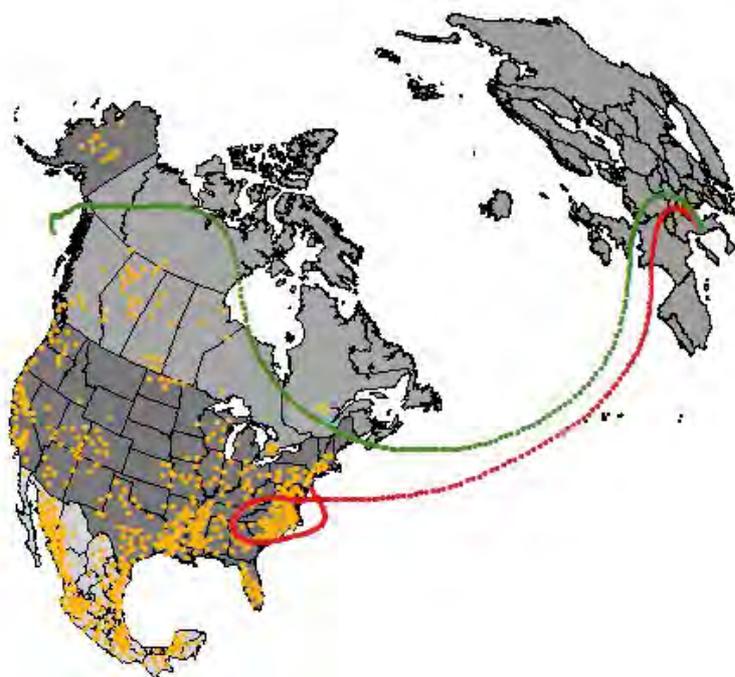

**Table 5.2. Mixing ratio variability from the flight samplings performed at the profile site around the maize field ground reference in the central Netherlands.**

	Mixing ratio					Range between days	
	Morning	Midday	Difference			Morning	Midday
CO <sub>2</sub> [ppm]	374.1	362.4	-11.7	-3.13 %	Summer	3.4	2.9
	378.7	377.4	-1.3	-0.34 %	Winter	4.5	2.7
	4.6	15.0			Difference		
CO [ppb]	176.8	153.7	-23.1	-13.07 %	Summer	91.2	61.5
	176.7	169.1	-7.6	-4.30 %	Winter	44.3	57.9
	-0.1	15.4			Difference		

Results obtained at the Italian mountain site (see chapters 4.1.6 and 4.2.3) allow identification of another source. Because of the SF<sub>6</sub> mixing ratios, which are not elevated, an anthropogenic dominated source area might be excluded.

Compared to terrestrial surfaces the oceans are characterised by a lower activity regarding combustion processes and anthropogenic emissions. Additionally, because of the low activity the gas composition can be conserved even during long range transports.

Thus, by the observed multiple tracer mixing ratios a contribution from far away from the study region could be identified (see also the discussion in chapter 4.2.3.3. 'Back Trajectory Calculations', p 88ff.).

**Figure 5.2.**

Fires detected by the MODIS sensor between 4 to 18 June 2002. Back trajectories of air particles calculated from a receiving point at the 2750 m sampling level above the 'Orvinio' location (Lazio / Italy) on 17 June 2002 21:30 UTC (red) and on 18 June 2002 11:30 UTC (green).

### 5.1.2. Comparison of the study regions

With respect to the aims of the RECAP project, the ‘qualification and quantification of sources’ and the ‘carbon budgeting of regional scales’, multiple tracer analyses are also providing basic information. Because of the characteristic composition of the air and due to the characteristic relationship of the individual trace gases regional and seasonal behaviours can be distinguished: the nature of the source and its type, the annual cycle and the geographical location.

## SEASONAL VARIATIONS AND LONGITUDINAL DIFFERENCES

### 5.1.2.1. Seasonal Variations

At the Hainich site flights have been performed in 2000, 2001 and 2002 during July and August (see table 5.3.) from which conclusions might be drawn regarding the range of the inter annual variability. A strong diurnal variation could be observed in 2001, while during the other years the CO<sub>2</sub> variability is depressed to one third of the values documented in 2001. But high variations of the mixing ratios between the days were recorded during all campaigns. A corollary of this observation is that there is a high ‘potential of uncertainty’ resulting from the limited number of available flight data for the analyses, which has to be considered for the interpretation.

**Table 5.3. Interannual and daily variability at the *Hainich* site (Thuringia / Germany)**

Values obtained by integration over the entire profile; Summer flights 2000 - 2003

	Mixing ratio				Range between days	
	Morning	Midday	Difference		Morning	Midday
CO <sub>2</sub> [ppm]	362.,7	360.8	-1.9	2000	0.7	0.4
	364.6	360.0	-4.6	2001	2.0	4.0
	368.6	367.2	-1.4	2002	6.8	5.6
	5,9	7,2		Difference		

As expected the observed absolute CO<sub>2</sub> mixing ratios were higher during winter time than in summer (see table 5.4). Responsible for this observation are mainly three factors: the absence of the CO<sub>2</sub> uptake by assimilation, the enhanced fossil

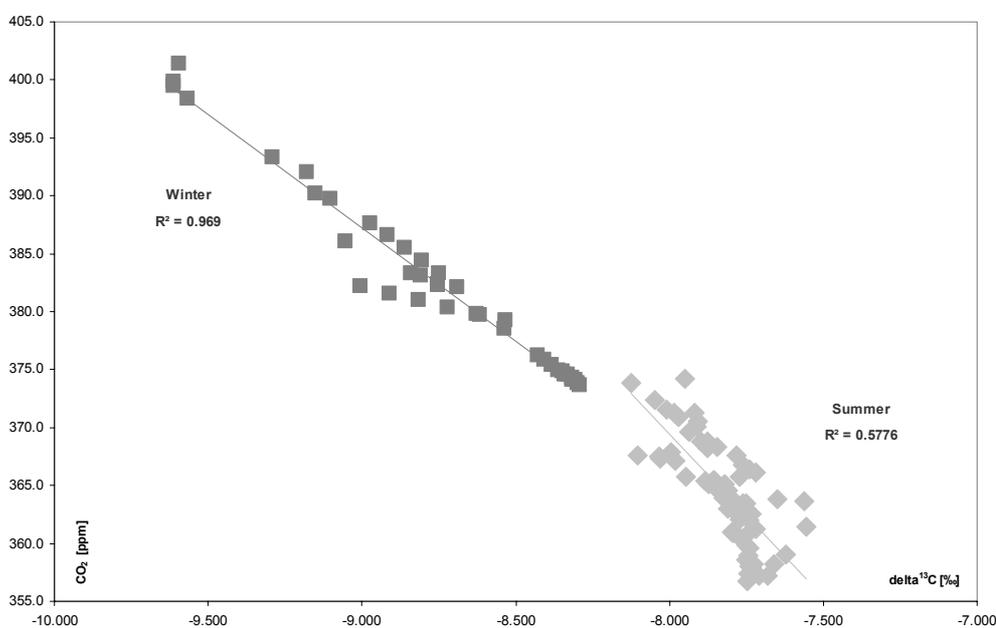

fuel emissions caused by the heating period and the higher accumulation rate within the shallower developed boundary layer in winter time.

**Table 5.4. Averaged seasonal data from flights performed above the *Hainich* and *Gebesee* sites during 2000 – 2002 (Thuringia / Germany)**

Only samples taken below 1500 ft altitude are included

	August	October	January	May
<b>CO<sub>2</sub> [ppm]</b>	364.3	377.5	384.3	375.3
<b>CH<sub>4</sub> [ppb]</b>	1844.7	1893.5	1874.6	1851.5
<b>N<sub>2</sub>O [ppb]</b>	319.3	319.0	318.5	319.4
<b>delta<sup>13</sup>C [‰]</b>	-7.783	- 8.147	-8.826	-8.449
<b>delta<sup>18</sup>O [‰]</b>	-0.139	- 1.343	-1.878	—

The link between the contributions of CO<sub>2</sub> sources and sinks, the uptake during assimilation in summer time and the elevated fraction originating from fossil fuel combustion in winter, becomes obvious by a correlation analysis (see figure 5.3.). Regarding the diurnal cycle of the mixing ratio higher values occur during the photosynthetic active period. This can be attributed to a predominance of the assimilation over the respiration rate. It is also caused by the deeper CBL during day time in summer leading to stronger dilution of CO<sub>2</sub> from night time respiration.

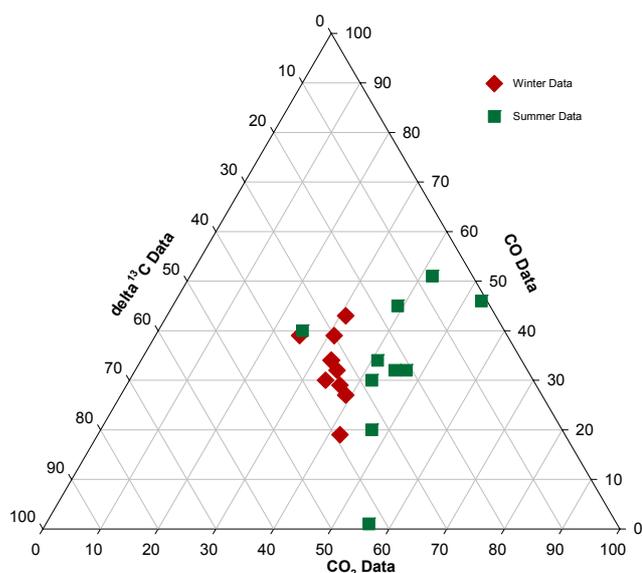

**Figure 5.3.** CO<sub>2</sub> / delta<sup>13</sup>C relation obtained from samples above the *Hainich* (Thuringia / Germany) during summer (light grey diamonds) and winter (dark grey squares) flights. Linear fits through the data points are applied. The discrimination for winter is -19.567‰ and for summer -28.099‰.

From the comparison of the seasonal results, as listed in table 5.4., a clear differentiation between summer and winter time is obvious. But when examining the data with respect to the  $\text{CO}_2$  /  $\delta^{13}\text{C}$  relation some problems become evident. The  $R^2$  values do not reflect the expected situation, that the correlation in summer and winter time should be nearly equal. During summer different biological sources, like plant and soil respiration are contributing to the  $\text{CO}_2$  inventory. In winter the  $\text{CO}_2$  originates from manifold strong anthropogenic contributors with a wide range of isotopic signatures (see table 5.1.). During the winter flights the contribution from fossil fuel emissions is high, obvious from the observations made on the flight to / from and at the study site. Thus a less depleted  $^{13}\text{C}$  signal should be expected, whereas from the flask samples a clearly enhanced  $^{13}\text{C}$  value compared to the summer data is derived (-19.567 ‰ winter time vs. -28.099 ‰ summer time).

Because of the insufficient characterisation, with respect to dynamic processes within the atmosphere, no definite estimation of the subsidence and free troposphere advection is possible. The most likely explanation is that the flask sampling during winter time was above the CBL within the lower free troposphere where the air is less affected by neighbouring surface processes. Additionally, because of the shallower CBL regional signals might be covered by local contributions (the 'regional rectifier'). A problem regarding the performance of flight sampling during winter arises: Due to aviation safety regulations the requested minimum flight altitude for low level samplings is not feasible.

An annual cycle can also be observed for the soil related processes, like the production of  $\text{N}_2\text{O}$  (see table 5.4). Since mainly microorganisms are responsible for the nitrogen conversion the reaction is strictly depending on the environmental conditions. The activity is affected therefore by soil moisture and soil temperature. Particularly at the beginning of the farming season fertilization increases the availability of nitrogen. Therefore highest  $\text{N}_2\text{O}$  mixing ratios were recorded in spring and summer time, whereas, caused by the reduced microbiological activity, lowest values were obtained during winter.

The discrepancies between the expected and the observed behaviour of the CO<sub>2</sub> and delta<sup>13</sup>C relationship are also recognizable from the comparison of summer- and winter-data obtained from the flights in The Netherlands (see figure 5.4). Less uniform relative ratios of CO<sub>2</sub>, delta<sup>13</sup>C and CO exist in summer. Especially prominent are two values; the one located close to the CO axis and the one close to the CO<sub>2</sub> axis. The first reflects the conditions of a sample taken during a morning flight: with high values of CO<sub>2</sub> and very high ones for CO, coming along with a low amount of delta<sup>13</sup>C. From the CO<sub>2</sub> and CO values a contribution from combustion processes might be suggested, but also the delta<sup>13</sup>C shows air enriched with the heavier isotope. Contrary to this unclear source the second conspicuous data point, calculated from a midday sample, gets an univocal source classification. High CO<sub>2</sub> and delta<sup>13</sup>C values combined with a low amount of CO are representative for respired air originating from a rural area.

**Figure 5.4.** Relative composition of CO<sub>2</sub>, CO and delta<sup>13</sup>C from flask samples taken in the free troposphere during the summer and the winter experiment in 'The Netherlands'. Displayed are data from morning and midday flights above the *Maize* and the *Cabauw* site. For the discussion of the data see the text above. Scale base for the gas species and the isotope values are defined by the observed ranges of both campaigns (see also Appendix A6).

	CO <sub>2</sub> [ppm]	CO [ppb]	delta <sup>13</sup> C [‰]
Cabauw / Maize	360.0 → 380.0	116.0 → 166.0	-7.750 → -8.500

### 5.1.2.2. Longitudinal Differences

Likewise of specific interest was the comparison of the areas belonging to same latitudinal zones within Europe. Since there are no significant data available from the Italian campaign to carry out a southern Europe examination, a longitudinal analysis was only practicable for the central European study sites 'Thuringia' and 'The Netherlands'.

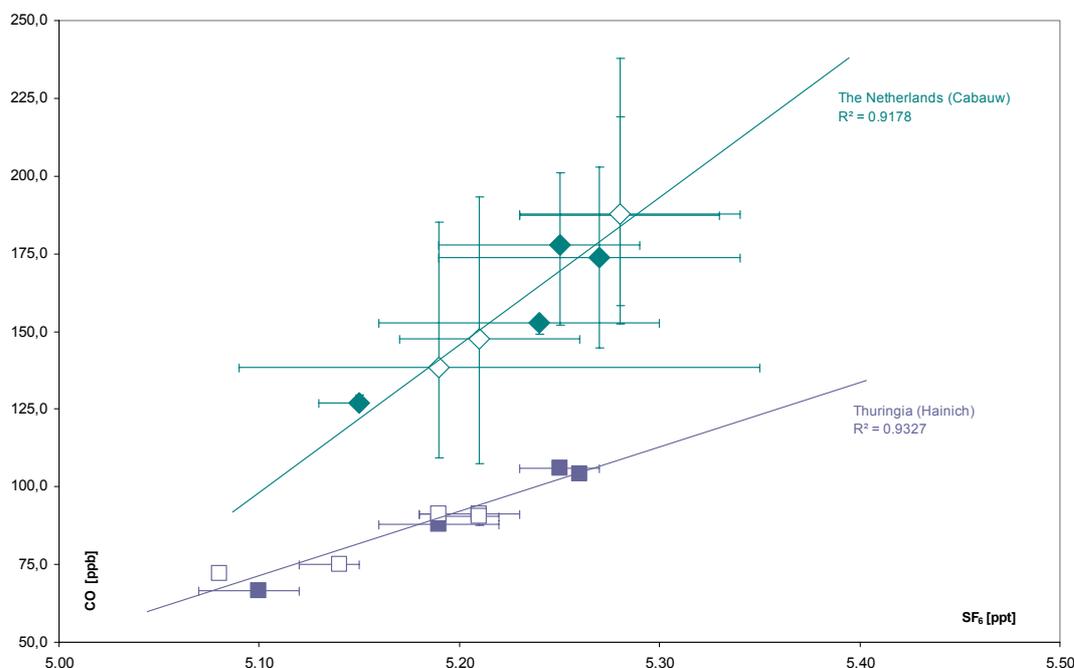

**Table 5.5. Averages of the CO<sub>2</sub> mixing ratios observed above the *Hainich* (Thuringia / Germany) and at the '*Maize*' study area (The Netherlands) during the winter and summer campaigns.**

	CO <sub>2</sub> mixing ratios [ppm]		
	Summer	Difference	Winter
Hainich (Thuringia)	364.3	20.0	384.3
'Maize' (The Netherlands)	368.3	9.8	378.1

With respect to CO<sub>2</sub> the most obvious difference between the areas can be seen in the amplitude of the annual cycle, whereas the simple mixing ratio mean is quite similar for both regions (see table 5.5). Because the Dutch area is even more urbanized than Thuringia, one should expect in particular for the winter season a slightly different result. An explanation for the observation might be given by the geographical conditions. Since the location of The Netherlands is less continental than the German study area the influence of air from marine origin is significantly higher (see also table 5.6). Because westerly and south-westerly winds are dominant for both regions a differentiation can be expected following the individual footprints. Thus the air masses sampled at the more continental 'Hainich site' should be transformed while passing over the land surface. Thereby, in summer time the CO<sub>2</sub> mixing ratio will be more and more reduced due to assimilation by plants, whereas during the winter the air might collect successively the released exhausts on their way eastwards.

More difficult is the situation when analysing the CO and SF<sub>6</sub> relationship of the summer data. Figure 5.5 presents the results from flights performed above the marshland site in The Netherlands in July 2002 and the data from the flights carried out above the Hainich during the SPA<sup>13</sup>CE experiment on 14 August 2002,

the day identified by multiple tracer comparisons (see figures 5.12. and 5.13.) and the modelling studies (see figure 4.30.) to be characterised by an air mass which has passed before also the Dutch area. When comparing the data displayed in figure 5.5 significantly higher CO, and slightly elevated SF<sub>6</sub> mixing ratios are observed at the marshland site.

**Figure 5.5.** CO / SF<sub>6</sub> ratios obtained from the flask samples at the *Cabauw* site (diamonds) during The Netherlands Summer Experiment on 16 and 27 July 2002 and above the *Hainich* (squares) during the SPA<sup>13</sup>CE Experiment on 14 August 2002 (Thuringia / Germany). Indicated are the individual flight levels for morning (solid symbols) and midday (open symbols) flights respectively. For both sites a linear regression was calculated.

The range of the observed maximum and minimum mixing ratios are indicated by the bars for SF<sub>6</sub> and CO. Notice that for the Hainich samples the range reflects the variance of the paired flasks, but for the Cabauw samples the range of two days. For CO the variance of the Hainich results is less than the symbol size.

As a reference possibly representative for both locations CO data from the marine background station 'MACE HEAD', Ireland (for location see figure 5.6.) can be taken. For June an average mixing ratio 103.21 ppb is reported, for August 118.97 ppb, respectively [data from CMDL CCGG]. Thus, lower mixing ratios should be expected from the samplings carried out at the Dutch marshland site. Therefore the question arose: Which fraction of the observed signal is contributed by regional

sources and which might be an effect of long range transport or chemical transformation?

The difference between the reference and the observed marshland data are indicating an importance of regional sources. Somewhere in between both sites the probable source area should be located. Since the data obtained from the flights performed above the Hainich on 15 August 2002 (which were characterised to be affected by passing across the UK) are not reflecting similar CO mixing ratios as observed at the marshland, a source located close to The Netherlands might be likely. A contribution from CH<sub>4</sub> conversion, originating from methane emission from tidelands, gas fields and marshlands also seems possible.

Regarding the differences between the Dutch and the German observations dilution processes might be of some importance. But when comparing the effects on SF<sub>6</sub> and CO: for the reduction of CO the contribution of additional processes has to be expected. A probable reaction could be the oxidation to CO<sub>2</sub>, which seems to be reflected by the high variance of sources contributing to the summer CO<sub>2</sub> signal as presented in figure 5.3.

## DIFFERENTIATION ALONG THE NORTH – SOUTH TRANSECT

### 5.1.2.3. Latitudinal Differences

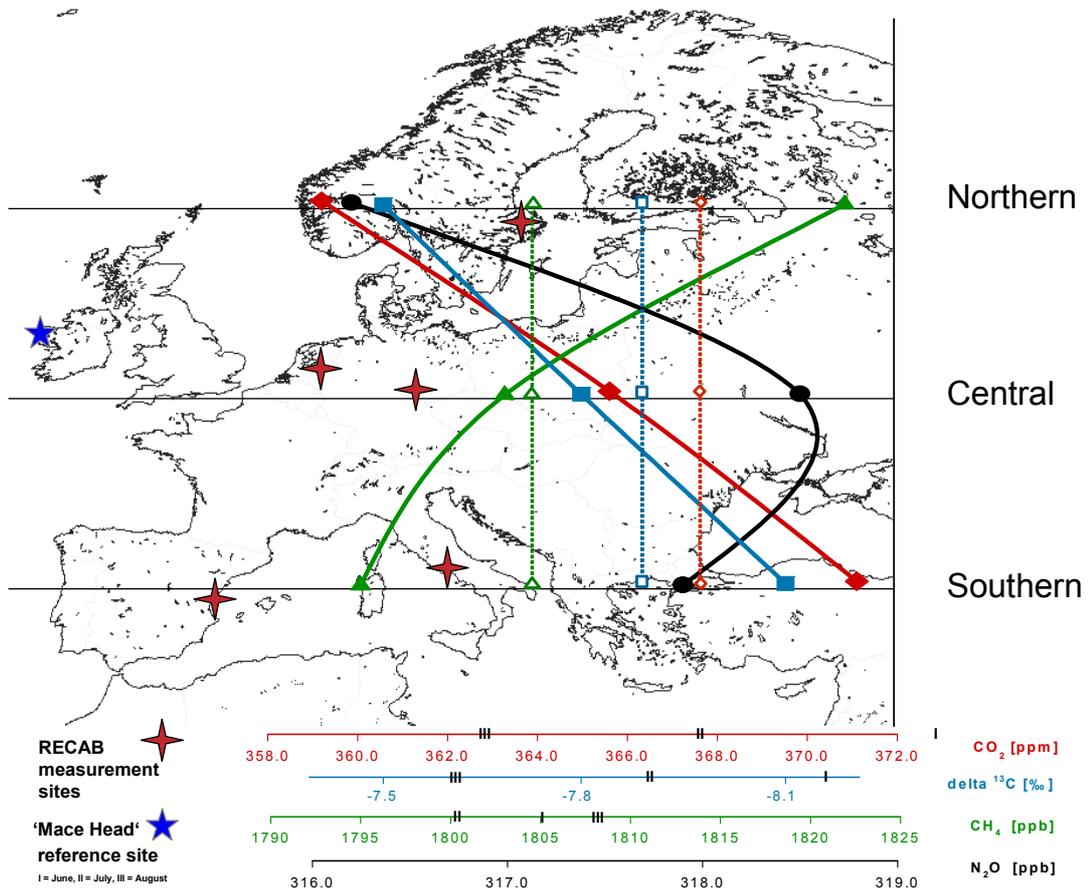

The 'RECAB study regions' can be differentiated by latitudinal criteria in three zones: the Uppland area within the northern band, the Valencia and the Latium sites defining the southern part and the Dutch and the German locations in between. When determining the individual sites one has to take into account that the composition of the air might be affected by different and locally specific processes, whereby a direct comparison focusing only on singular effects might be critical. Thus an influence by polluted air from industry is more characteristic and representative for a highly industrialized area as for a remote place. On the other side, CO formation from VOCs is more likely at a forest site, than within highly urbanized areas. Since it became obvious that local interferences are hindering a regional characterisation (see the analysis of the summer campaign in 'The Netherlands'), the comparison of the zones considers only data from the upper profiles. On the other hand the free troposphere data will as well not reflect the real 'regional' characters but more information of the entire zonal band the study site is belonging to.

Since the campaigns were not performed simultaneously CO<sub>2</sub>, CH<sub>4</sub> and delta<sup>13</sup>C data from the atmospheric research station MACE HEAD, Ireland (53°20'N / 9°54'W) are presented as an 'independent relation frame' (see figure 5.6). A distinct seasonal signal reflecting probably the contribution of assimilation from the CO<sub>2</sub> and delta<sup>13</sup>C data can be recognized, which seems to be congruent with the hypothesis regarding the effect of the time delay of the individual campaigns (see table 2.4, p. 22). But a similar distinct seasonality could not be observed for CH<sub>4</sub>.

However, it should be taken into account that the data do not offer a real and objective basis for comparisons, since the data themselves are affected by impairments. In this context the question about the significance of time delays seems to be of importance, in particular with respect to the reflection of signals from plant activity (see therefore chapter 5.2.). The influence of vegetation underlies per se inherent constraints – on a temporal basis and as well regarding spatial dynamics, following the progression of the phenological status from the south to north. Another aspect might be the spatial frame of synoptic processes,

on that account the comparability of the individual campaign regions with the reference station might be limited. Thus the 'Mace Head' data should not be taken noncritical as calibration values, but as additional hyper-regional information.

Comparing the results from the flask samplings of the summer campaigns a significant north-south gradient becomes obvious (see figure 5.6.). The CO<sub>2</sub> mixing ratios and isotope composition are reflecting the effect of the vegetation at the Swedish locations, while the results from central and southern Europe are characteristic for more urbanized areas. Intermediate values are obtained from the central sites. As expected from the natural environment, since potential sources like swamps are wide spread in Scandinavia, highest CH<sub>4</sub> mixing ratios were measured at the northern location.

**Figure 5.6.** Summer campaigns: Averaged values of the measured mixing ratios of CO<sub>2</sub> (diamonds), CH<sub>4</sub> (triangles), N<sub>2</sub>O (circles) as well as the delta <sup>13</sup>C in CO<sub>2</sub> (squares) for the three European zones. Only data sampled within the free troposphere have been taken, to avoid perturbations by local contaminations. By the open symbols the mean values calculated for the 'background reference site' MACE HEAD are indicated. On the individual mixing ratio axis the monthly means are marked [2001 / 2002; Data from CMDL CCGG].

Regarding the N<sub>2</sub>O mixing ratio a different gradient is being observed. The highest values occur in Central Europe. This can be related to the formation process of N<sub>2</sub>O, which is primarily released from moderately moist soils. At the southern locations very dry conditions inhibited microbiological activity, whereas in the northern parts the soils were partly less drained. The higher percentage of agricultural areas and the potentially additional input of nitrogen by fertilizing might also be a contributing factor for the enhanced values which were observed at the Central European sites.

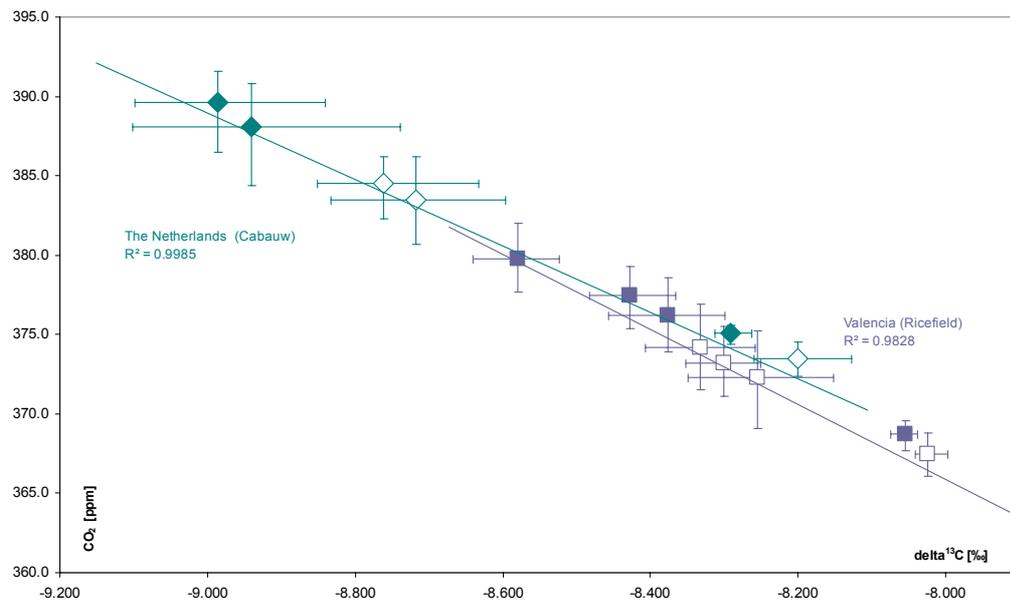

During winter time only the locations in The Netherlands, in Germany and in Spain were sampled (see table 5.6). Contrary to the summer data the lowest CO<sub>2</sub> mixing ratios were measured at the Valencia site. The reduced values in the southern part are reflecting the still active vegetation, since the weather was fine when the campaign took place and the temperatures were above 15°C. Therefore also emissions from heating were reduced, compared to Central Europe, where the temperatures were lower (The Netherlands: about 10°C, Germany: below 0°C).

**Table 5.6. Comparison of the mixing ratios obtained from the winter campaign flights in Central Europe (Thuringia and The Netherlands) and in Southern Europe (Valencia). Samples were taken within the free troposphere.**

	CO <sub>2</sub> [ppm]	δ <sup>13</sup> C [‰]	CH <sub>4</sub> [ppb]	N <sub>2</sub> O [ppb]
<i>Thuringia</i>	380.6	-8.553	1841.1	317.8
<i>The Netherlands</i>	375.7	-8.331	1827.3	318.4
<b>Central (Average)</b>	<b>378.2</b>	<b>-8.442</b>	<b>1834.2</b>	<b>318.1</b>
<b>Valencia</b>	<b>368.3</b>	<b>-8.072</b>	<b>1808.0</b>	<b>318.1</b>

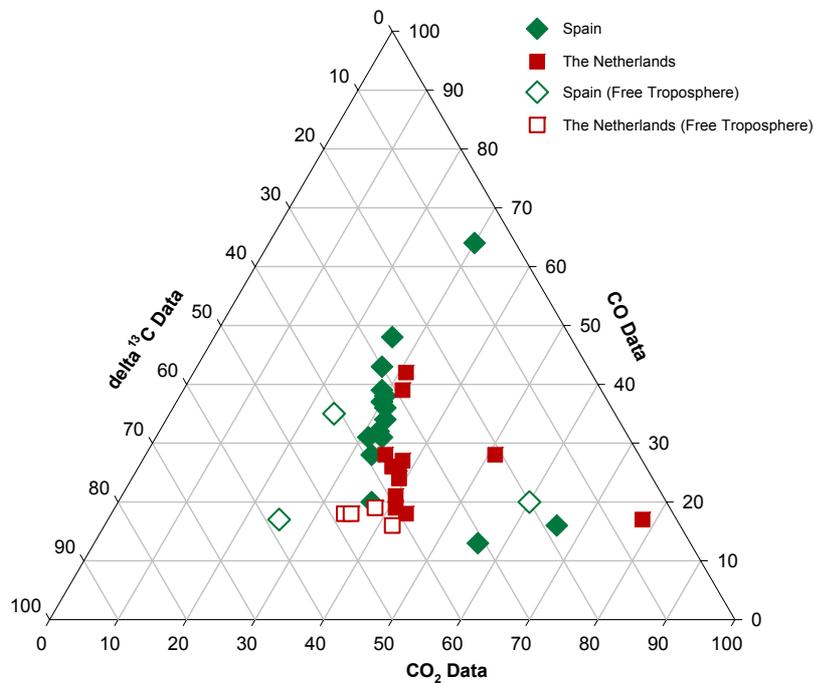

That a part of the differences between the German and the Dutch region might also be attributed to the temperature discrepancy becomes in particular obvious from the N<sub>2</sub>O data, reflecting the inhibition of the microbiological activity in the frozen German soils. In addition a significant contribution of the differences can be attributed to longitudinal effects, as described earlier in the context of the seasonal variations.

Figure 5.7 presents the relationship between  $\text{CO}_2$  and  $\delta^{13}\text{C}$  obtained from flights carried out above the marshland in The Netherlands and the rice fields in Spain. Distinctly higher  $\text{CO}_2$  mixing ratios and more negative  $\delta^{13}\text{C}$  values were observed at the Dutch region. From the data source discrimination characteristics of  $-27.454\text{‰}$  (The Netherlands) and  $-24.546\text{‰}$  (Spain) can be calculated, pointing to a stronger impact of anthropogenic emissions and reduced assimilation in The Netherlands.

**Figure 5.7.**  $\text{CO}_2$  /  $\delta^{13}\text{C}$  relation obtained from samples taken at the *Cabauw* site (green diamonds) during The Netherlands Winter Experiment on 30 January 2002 and 2 February 2002 and from the *Rice* field site (blue squares) during the Valencia Winter Experiment on 5 and 6 December 2001 for morning (solid symbols) and midday (open symbols) flights, respectively.

The differentiation of both study regions by a differing  $\text{CO}_2$  and  $\delta^{13}\text{C}$  relation is also reflected in figure 5.8, which adds CO information. The solid symbols represent samples taken within the CBL and open ones the free troposphere. Besides the wide range of the CO fraction at both locations a high variability of the tracer relation in the Spanish ‘free troposphere’ is obviously caused by contributions from different sources. Local contamination is indicated by the outliers sampled within the CBL. Thus affections are important which are not comparable with a budgeting of the regional scale.

**Figure 5.8.** Relative composition of CO<sub>2</sub>, CO and delta<sup>13</sup>C from flask samples taken during the winter experiments in Spain (*Rice field*) and The Netherlands (*Forest and Maize*). The results presented in this figure are discussed in the text section above. Scales for the CBL are defined by the observed ranges of the individual campaigns, but for the 'Free Troposphere' by both experiments (see also Appendix A6):

	CO <sub>2</sub> [ppm]	CO [ppb]	delta <sup>13</sup> C [‰]
Forest / Maize (The Netherlands)	373.0 → 383.0	127.5 → 247.5	-8.250 → -8.700
Ricefields (Spain)	364.0 → 374.0	105.0 → 225.0	-8.000 → -8.450
Free Troposphere	367.5 → 379.5	110.0 → 170.0	-8.030 → -8.480

## 5.2. Theoretical and Conceptual Aspects

A basic idea of the budget approach is to use the difference in the mixing ratio obtained from two measurements as a measure to calculate fluxes. Thus the environmental conditions at both sample times should be identical.

### 5.2.1 TIME DEPENDENCE

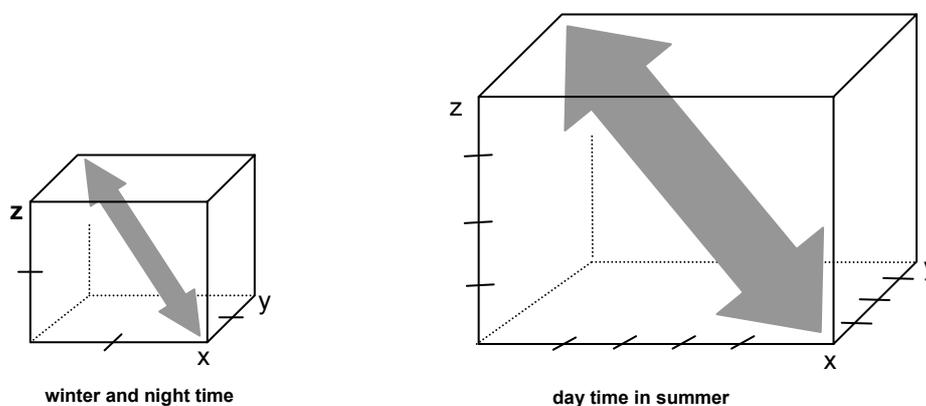

When analysing biological contributions to mixing ratio changes CBL and vegetation dynamics have to be taken into account. These dynamics as a function of solar irradiance are intensively discussed in the literature [DENNING et al. 1995, BAKWIN et al. 1998, DENNING et al. 1999, STEPHENS et al. 2000]. In this study it affects mainly the diurnal and seasonal comparisons. In summer both parameters are negatively correlated. When CO<sub>2</sub> mixing ratios reduced through assimilation by plants CBL height reaches its maximum during its yearly cycle. In contrast, in winter the shallower CBL accumulates the respired CO<sub>2</sub>.

**Figure 5.9.** Scheme for the time dependence of CBL height and carbon source/sink activity. The left box presents the situation dominant for winter and night time, characterised by a shallow CBL. The right one a summer day near noon. An extended CBL height comes along with high CO<sub>2</sub> uptake by vegetation and low anthropogenic emissions.

The vertical dilution affects not only near surface measurements but also data from continuous profiles. Beyond this effect another phenomenon affects the budgeting

approach. Since the CBL is defined as a nearly closed integration chamber, also the varying spatial dimension of the monitored area needs to be considered.

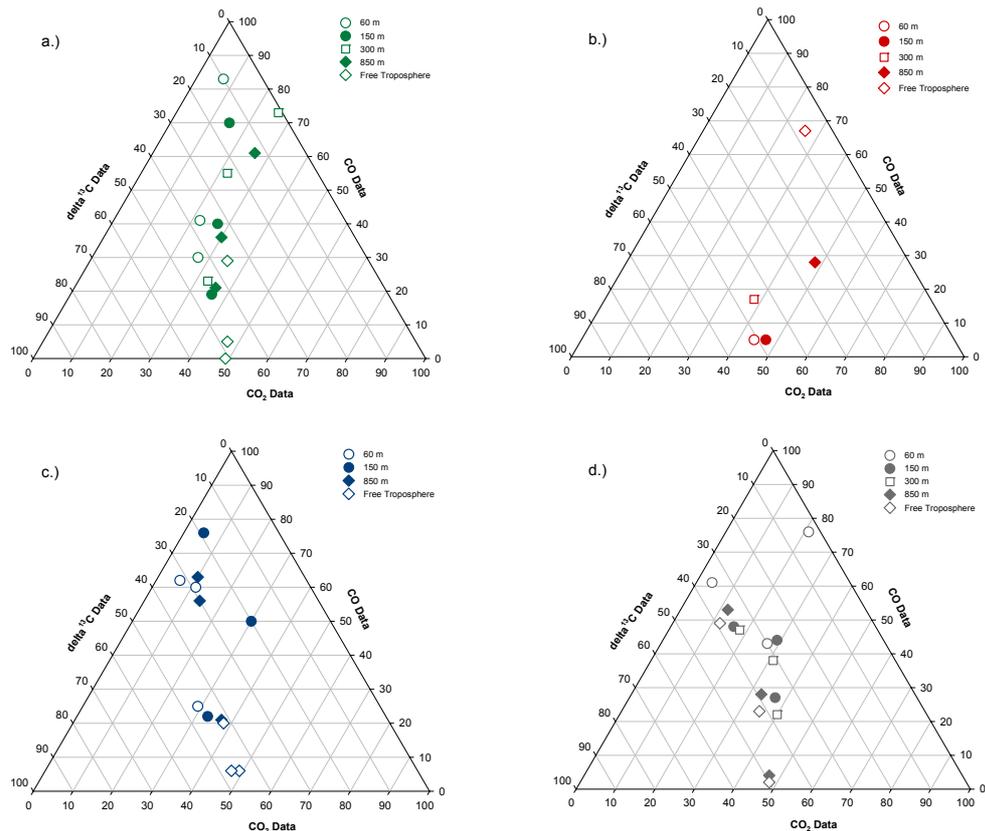

**Figure 5.10.** Relationship between CBL height and extension of the footprint. On the left a shallow CBL with a small footprint area is presented typical for winter and night time conditions. The situation for a summer day is shown by the right box, where an extended CBL height enlarges the 'footprint'. The dimension of the source area is indicated by the arrow size.

The influencing region on a summer afternoon will be much larger than on a winter morning. The spatial extent of the influencing *region* may vary from nearly local, to regional, to continental, and occasionally even to global scale. Accordingly each concentration profile describes different areas. Because of this relationship between temporal and spatial extension one might define this effect as a 'regional rectifier'.

In this context the uncertainty arose how to fix the flight levels, in particular for the first morning flights. It could be shown that frequently the residual air from the day before was sampled instead of a shallow CBL, missing a major portion of respiration. To sample morning air from a larger area a compromise had to be found: On one hand a sampling height as low as possible was required, to gain information from the CBL reflecting the respiration character. However, the flight time had also to be chosen as late as possible, to sample air of an extended CBL column, representing a regional area. In consequence during summer the starting time had to be fixed with sunrise, which is also the earliest time permitted by the aviation regulations. During winter the starting time was scheduled around two hours after sunrise.

## VARIABILITY - AIR MASS CHANGE

By the multiple tracer analyses air with distinctly different compositions could be identified between repeated samplings at one location. Because of the forced rapid changes of the mixing ratios the samplings were most frequently not comparable. The consequence of this was that fluxes and budget calculations for the study regions could not be achieved.

**Figure 5.11.** Relative composition of CO<sub>2</sub>, CO and delta<sup>13</sup>C from flask samples taken at a) Florarna (Uppland / Sweden), b) Tuscania (Lazio / Italy), c) 'Maize' (The Netherlands) and d) Hainich (Thuringia / Germany; SPA<sup>13</sup>CE experiment). Scale basis for each gas species and the isotope values are defined by the observed ranges of the individual campaigns:

	CO <sub>2</sub> [ppm]	CO [ppb]	delta <sup>13</sup> C [‰]
Florarna (Sweden)	349.0 → 359.0	106.0 → 136.0	-7.035 → -7.635
Tuscania (Italy)	369.0 → 379.0	125.0 → 185.0	-8.100 → -8.400
Maize (The Netherlands)	360.0 → 370.0	105.0 → 205.0	-7.550 → -8.050
Hainich (SPA <sup>13</sup> CE, Germany)	361.5 → 371.5	70.0 → 130.0	-7.550 → -7.950

Variability of air composition as well as of individual gas mixing ratios could be observed according to several aspects: on a spatial basis, e.g. by stratified sampling levels, by different locale profile sites within the study regions and by the diverse regions (see figure 5.11, Appendix A6), on a temporal basis, exemplified by rapid and diurnal changes or by variations on a day-to-day, a seasonal or an inter annual time scale.

### Day-to-day Variability

On two consecutive days of the SPA<sup>13</sup>CE experiment different air masses could be observed. A classification to probable source areas could be achieved from multiple tracer analyses and modelling investigations (see also chapters 4.2.8.1. and 4.8.2.2.).

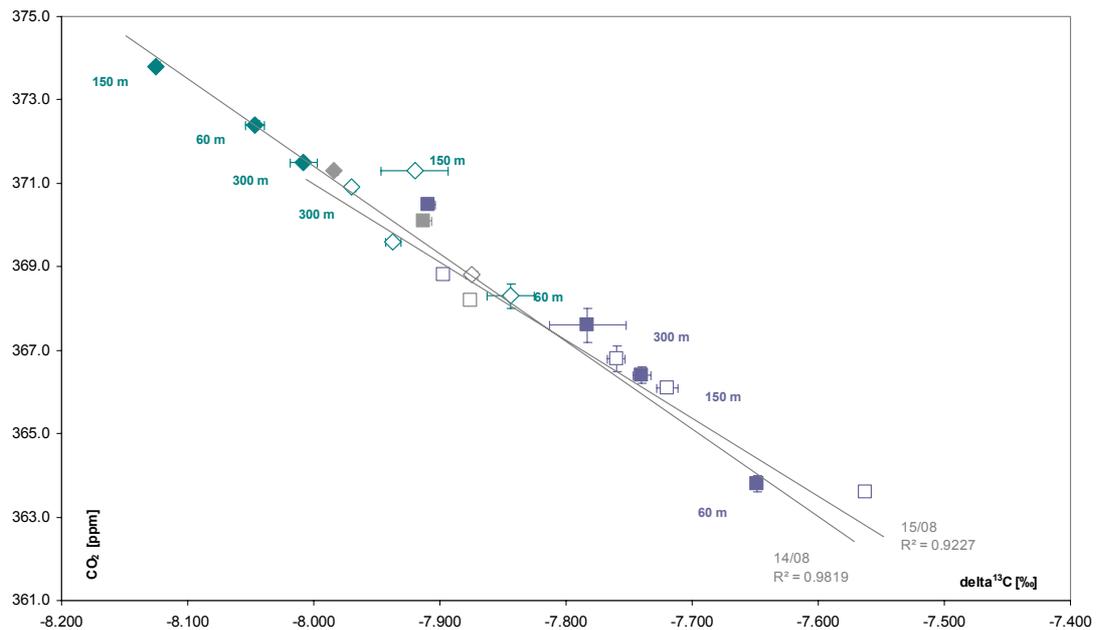

Figure 5.12 presents the CO and SF<sub>6</sub> mixing ratios from both days (solid symbols 14 August 2002, open symbols 15 August 2002; green: morning data, blue: data from midday flights).

**Figure 5.12.** CO / SF<sub>6</sub> relation obtained from the flask samplings performed during the SPA<sup>13</sup>CE experiment on 14 and 15 August 2002 above the *Hainich* (Thuringia / Germany). The flight levels are indicated by green diamonds for morning flights (solid 14, open 15 August 2002), and blue squares for midday data. A linear regression was calculated for both days. The bars for SF<sub>6</sub> and CO indicate the paired flasks.

A higher mixing ratio of both trace gases is clearly noticeable on 15 August 2002. As the formation of SF<sub>6</sub> is related to anthropogenic activity and CO production occurs during combustion processes and from conversion of biogenic precursors a significantly higher contribution from terrestrial sources is reflected by the data. Also the lower explained variance compared with the results from the 14 August suggests the input from several different sources.

An equal finding can be obtained from the analysis of the relationship between the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values, while a lower R<sup>2</sup> suggests a contribution from several different sources on 15 August 2002. This day a lower CO<sub>2</sub> mixing ratio is associated with slightly more negative delta<sup>13</sup>C values. For 14 August 2002 a discrimination of about -25.649 ‰ can be calculated, against a discrimination of about -26.846 ‰ for 15 August 2002 which might reflect an increased input from fossil fuel consumption and assimilation activity.

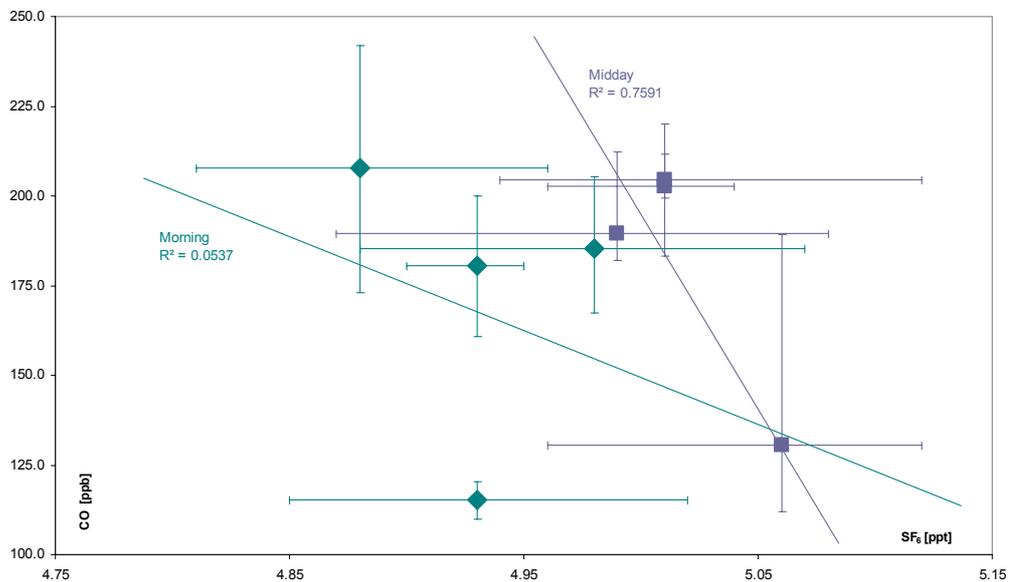

**Figure 5.13.** Mean mixing ratios of CO<sub>2</sub> and delta<sup>13</sup>C from each flight level and of the entire profiles from the flights performed within the SPA<sup>13</sup>CE experiment above the *Hainich* study site (Thuringia / Germany) on 14 and 15 August 2002. Morning results are shown as green diamonds (solid 14, open 15 August 2002), the midday data as blue squares. Linear regressions were calculated for both days. Discrimination values are: 14/08/2002 (-25.649 ‰) and 15/08/2002 (-26.846 ‰). The error bars are indicating the range of the mixing ratios between paired flasks.

These differences were also confirmed by ground level sampling (see figure 4.17). However, since advection affects the entire profile, a disturbance and concealment of the canopy contribution by air mass change can not be excluded. It is, therefore still difficult to distinguish which part of the signal is of local origin and which can be assigned to air mass change because of advection.

### Local Characteristics - Land-Sea-Wind Circulation

Beside the identification of exchange processes on a day-to-day time scale, which was achieved by using multiple tracer data, the detection of disturbances within a diurnal cycle became also possible. The affection by periodical circulation schemes shall be demonstrated on the basis of the results from the Valencia field experiments.

Due to its geographical location at the shore of the Mediterranean Sea a distinct diurnal land-sea-wind circulation scheme can be observed. During day time the terrestrial surface is heated stronger by solar irradiance. This is in conjunction with convection above the land and a draft directed downwards creates an onshore wind. In contrast during the night, the warmer water body causes an offshore wind. The resulting wind is collaterally affected due to the local topography. Within the valleys directed orthogonal to the Mediterranean Sea an amplification is induced. Figure 5.14 presents the CO / SF<sub>6</sub> relationship during two days of the winter campaign. A clear difference between morning (green diamonds) and midday data (blue squares) becomes obvious. In particular for the midday results distinctly higher SF<sub>6</sub> and slightly elevated CO mixing ratios can be recognized.

**Figure 5.14.** CO / SF<sub>6</sub> relation obtained from flask sampling above the *Rice* field site at the Valencia Winter Experiment (Spain) on 5 and 6 December 2001. Indicated are the individual flight levels for morning flights (green diamonds) and midday flights (blue squares) flights. For both dates a linear regression was calculated. The range of the observed maximum and minimum mixing ratios is indicated by the bars for SF<sub>6</sub> and CO.

From this a classification of the source origin can be achieved: the relatively high SF<sub>6</sub> mixing ratios observed by the midday data indicate a contribution from anthropogenic sources. Also, the slightly elevated CO mixing ratios point to a terrestrial influence. Emissions from human activity contribute to the air mass while floating inland. In contrast, the morning samples were performed in the downdraft which takes air of marine origin inland.

This exchange process can also be seen from the relationship between the CO<sub>2</sub> mixing ratio and the delta<sup>13</sup>C values. Results from the ground level samplings are presented in subchapter 5.4.1. (see figure 5.21).

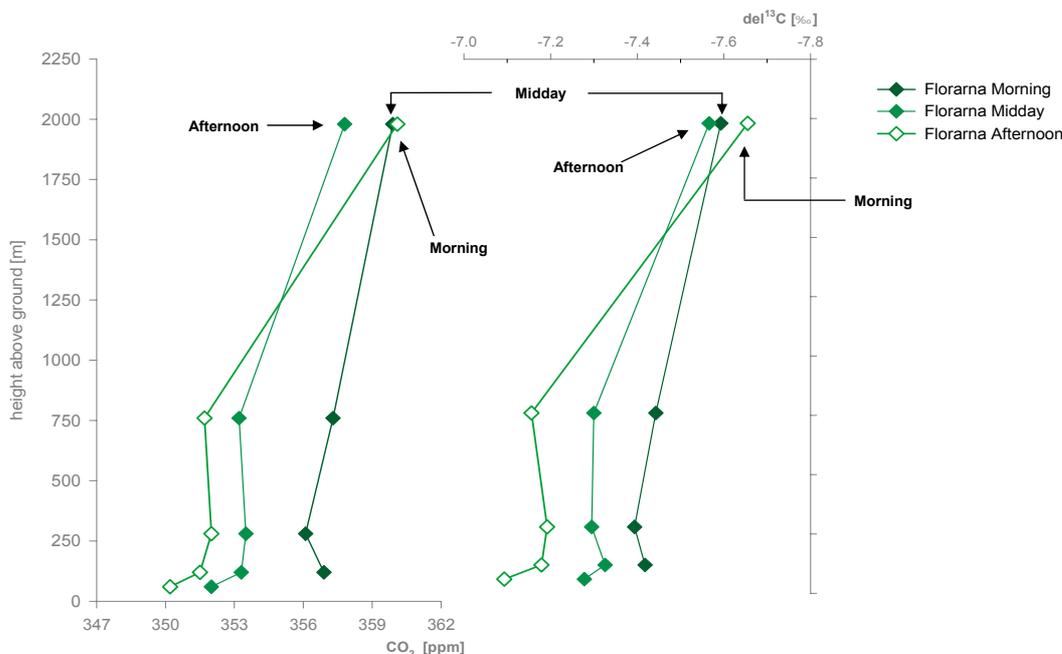

Since the effects caused by advection or by local events frequently exceeded the expected amount of the natural provoked values, the process of air mass change must be taken into account. This means that the geographical location in particular has to be considered, because of the effects forced by topography (see also chapter 4.2.8.1., pages 107f) and diurnal circulation schemes.

#### *'SIGNAL SHIFT' – EFFECTS OF TIME DELAYED DETECTION*

The interaction of temporal and spatial components determines an additional aspect that has to be taken into account. This was examined by the Swedish flight profiles from 30 August 2001.

Figure 5.15 displays the three profiles sampled during the day, showing within the CBL the typical diurnal cycle with an uptake of CO<sub>2</sub> by the vegetation. In contrast, the 'background' data from the free troposphere presented a distinct change in the afternoon when a significant increase of the CO<sub>2</sub> mixing ratio was observed, concomitant with a relative depletion of the <sup>13</sup>C content. By ascribing this variation to air mass change caused by advection, two reasons for the composition of the afternoon signal have to be discussed: 1) the air originates from a different, urban source area, or 2) the air originates from a different source area, but of the same land use type. The change observed by the afternoon data will then be an effect of different formation processes, i.e. the sample represents a respiration signal.

When assuming that the afternoon sample is characterised by respiration one can replace the morning sample by this data. Consequently, the other two data sets can also be exchanged to adapt the free troposphere signal to the profiles obtained from the CBL, leading to the substitution scheme: afternoon (real) → *morning (notional)*, morning becomes *midday* and midday becomes *afternoon*.

**Figure 5.15.** Time delayed detection of ‘formation specific’ CO<sub>2</sub> and delta<sup>13</sup>C signals observed on 30 August 2001 above the Florarna site (Uppland / Sweden). The afternoon sample taken in the free troposphere shows a composition typical for respiration. For description of the calculation and shifting scheme see text.

Estimating the order of a probable uncertainty regarding flux calculations from a comparison between the real observed data and the data set with the adapted classification the following can be said: the depletion of CO<sub>2</sub> during the day obtained from the observation can be mentioned to be -3.1 ppm versus a rate of -4.9 ppm derived from the changed classification, equivalent to flux rate differences like  $-16.8 \mu\text{mol m}^{-2} \text{s}^{-1}$  to  $-26.5 \mu\text{mol m}^{-2} \text{s}^{-1}$ . This means that a calculation based on the *observed* profile will underestimate the hypothetical, but rather plausible, value by about 40%. Relating this result to the uptake of carbon by vegetation, a further brief calculation gives an indication regarding the sensitivity of inventories. Within the period of a growing season (defined here by a time frame of 100 days with 8 hours per day uptake by vegetation) a flux of

$1\mu\text{mol m}^{-2} \text{ s}^{-1}$  is equivalent to a carbon uptake of about  $350 \text{ kg ha}^{-1} \text{ season}^{-1}$ . For instance, the net annual carbon fixation of European forests studied by the CarboEurope project 'Forest Carbon Nitrogen trajectories' (FORCAST) is in the main between 3 and  $6 \text{ t C ha}^{-1} \text{ a}^{-1}$  [MUND, *personal communication*].

By the occurrence of the combination of temporal driven processes and advection, which itself has a time depending component, crucial uncertainties might be provoked. Thus one also has to take this relationship into account when analysing effects provoked by reactions between gases and removal depending on deposition processes.

#### *CH<sub>4</sub> AND VOC CONVERSION*

Even at the Swedish site, characterised by a land cover of less heterogeneity and a low contamination potential, a high variability of the mixing ratios could be observed (see table 5.7). Beside the enforced changes due to air mass replacement by advection, modifications can also be caused by chemical reactions between certain compounds. For some of the observed trace gases transformation is even the major terrestrial sink – or on the other side a not negligible source.

**Table 5.7. Relative change of the mixing ratios observed above the *Florarna* site (Uppland / Sweden) on 30 August 2001**

(expressed in percent from morning to midday, from midday to afternoon and from morning to afternoon flights respectively; calculated from data sampled within the entire CBL column)

	<b>CH<sub>4</sub></b>	<b>CO<sub>2</sub></b>	<b>CO</b>	<b>SF<sub>6</sub></b>	<b>H<sub>2</sub></b>
Morning → Midday	-0.02	-2.51	+3.45	-0.61	+0.07
Midday → Afternoon	+2.96	-0.45	-1.26	+1.43	-1.13
Morning → Afternoon	+2.80	-3.04	+2.16	+0.81	-1.07

In addition to combustion processes, CO can also be produced by the conversion of CH<sub>4</sub> and from VOCs. The destruction of CH<sub>4</sub> depends mainly on the reaction with the OH radical (see reaction chain 2.1.2.11 ff.). Because of the very high CH<sub>4</sub> mixing ratio occurring at the wetland site and due to the percentage of CO formation described from CH<sub>4</sub> conversions to be about 20% (see table 2.1), a probable contribution by this pathway has to be quantified. Figure 5.16 presents

the correlation between CH<sub>4</sub> and CO mixing ratios, suggesting a principal relationship ( $R^2 = 0.6629$ ).

Based on the samplings carried out at the Florarna site CH<sub>4</sub> conversion rates were calculated using different reaction coefficients (uniform 298K and 760 Torr) and concentrations for OH.

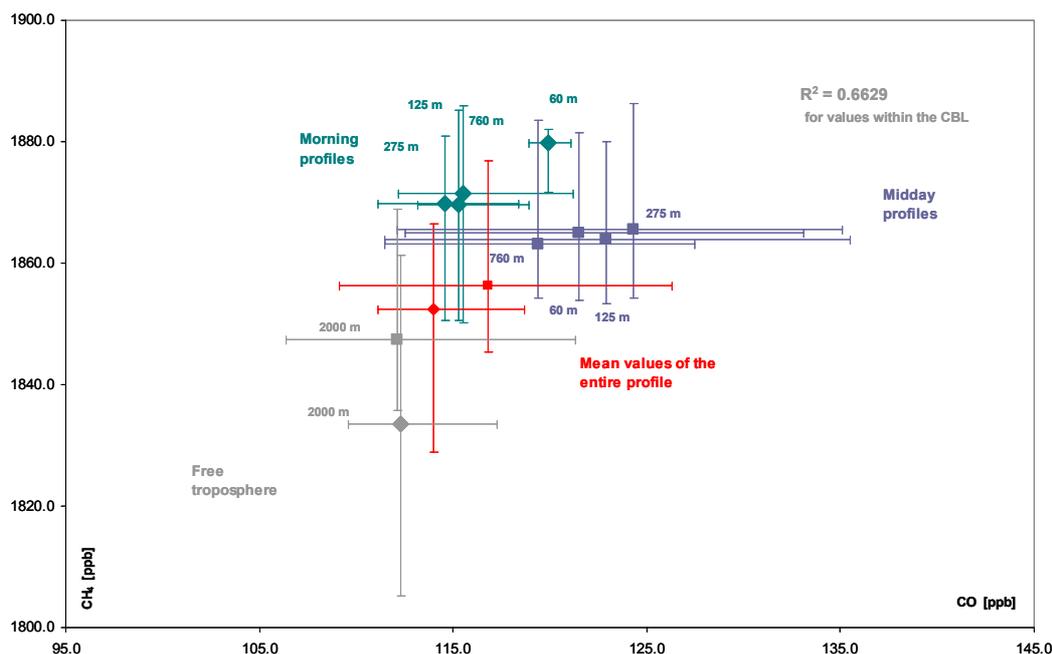

Because of the observed variability within the diurnal time frame (see for instance table 5.7) and on a day-to-day time scale (indicated by the bars in figures 5.1., 5.16 and 5.17), averages from the three days of morning and midday flights were used for the estimations (see table 5.8).

**Table 5.8. Averaged mixing ratios used for calculation of the conversion rates**

	<b>Morning</b>	<b>Midday</b>	<b>Difference</b>
<b>CH<sub>4</sub></b>	1872.0 ppb	1864.3 ppb	-7.7 ppb
<b>CO</b>	115.9 ppb	121.8 ppb	+5.9 ppb
<b>CO<sub>2</sub></b>	358.4 ppm	352.1 ppm	-6.3 ppm

The rate of the destroyed CH<sub>4</sub>, i.e. of the formed CO, varied between 198 ppt h<sup>-1</sup> (with  $k = 4.9 \cdot 10^{-15} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$  [WARNECK 2000] and  $\text{OH}_{\text{conc.}} = 6 \cdot 10^6 \text{ mol cm}^{-3}$ ) and 558 ppt h<sup>-1</sup> (with  $k = 8.4 \cdot 10^{-15} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$  [Atkinson 1989] and  $\text{OH}_{\text{conc.}} = 1 \cdot 10^7 \text{ mol cm}^{-3}$ ). During the period between both flights of about 5 hours the total of the transformed CH<sub>4</sub> can be assumed to be in the order of ~ 1ppb to 2.8ppb. These amounts explain 13 – 36% of the observed CH<sub>4</sub> depletion, but 17 – 47% of the formed CO.

A second chemical formation of CO, with a contribution of about 20% in the same order as reported for CH<sub>4</sub> (see table 2.1), is the oxidation of volatile organic compounds (VOCs). VOCs originate mainly from biogenic processes (see table 5.9), in which emissions from foliage represent the primary source. The two prominent classes are monoterpene, which originates mostly from coniferous species, and isoprene, released substantially by deciduous plants and as well as from wetlands [JANSON and DE SERVES 1999].

**Figure 5.16.** CH<sub>4</sub> / CO relation from samples above the *Florarna* nature reserve (Uppland / Sweden) on 29 and 30 August and 1 September 2001. Indicated are the means for the individual flight levels for morning (solid diamonds) and midday (solid squares) flights, and of the entire profiles. Ranges of the mixing ratios during all days are indicated by the bars for CH<sub>4</sub> and CO. For the calculation of the explained variance only samples taken within the CBL are considered, with the exception of the morning 60 m data, which were excluded (see also figure 5.1).

Because the reaction rate of OH radicals with VOCs is much higher than with CH<sub>4</sub>, and high VOC mixing ratio occurs in the boreal zone during summer, a relevant contribution by this pathway can be assumed. It is, however, difficult to give an estimate, since VOCs were not part of the analytical scheme of RECAP. The calculation is, therefore, only a rough indication for this formation way.

**Table 5.9. Summary of Global emissions of Hydrocarbons and Other Organic Volatiles from Various Sources** (from Warneck 2000)

Anthropogenic Sources	Emission rate (Tg/a)
Petroleum related and chemical industry	36 – 62
Natural gas	2 - 14
Organic solvent use	8 - 20
Biomass burning	25 – 80
<b>Total anthropogenic sources</b>	<b>71 - 175</b>

<b>Biogenic Sources</b>	<b>Emission rate (Tg/a)</b>
Emissions from foliage	
Isoprene	175 – 503
Monoterpenes	127 – 480
Other organic compounds	510
Grassland	< 26
Soils	< 3
Ocean waters (light alkanes and alkenes)	2.5 - 6
Ocean waters (C <sub>9</sub> – C <sub>28</sub> alkanes)	< 26
<b>Total biogenic sources</b>	<b>815 - 1530</b>

But measurement results from this region are available from the 'BIPHOREP project' (*Biogenic VOC emissions and photochemistry in the boreal regions of Europe*).

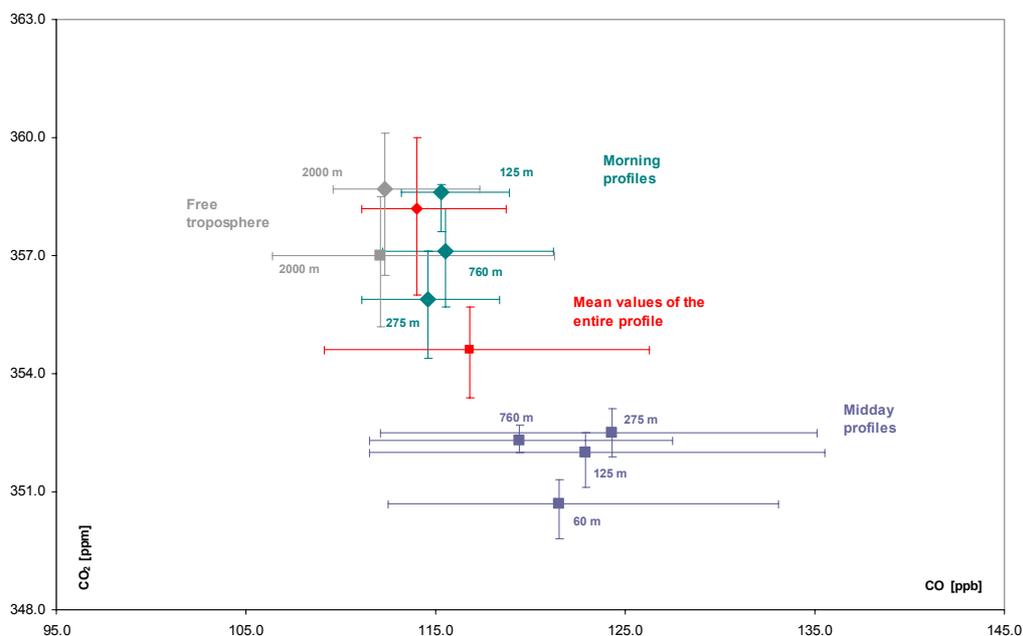

Studies focussing on VOC emission and transformation were performed around the Norunda field site (Sweden) and at different regions in Finland in 1996 and 1997. For the calculation of a supposable CO formation from VOCs data were used adapted to mixing ratios reported by LAURILA et al. [1999] for the 'Mekrijärvi' field site in south-east Finland. According to the isoprene emissions from wetlands reported by JANSON and DE SERVES [1999], a VOC mixing ratio of 750 ppt propylene-equivalent [CHAMEIDES et al. 1992] is assumed.

With a reaction rate  $k = 2.6 \cdot 10^{-11} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$  [Atkinson 1989] and  $\text{OH}_{\text{conc.}} = 1 \cdot 10^7 \text{ mol cm}^{-3} \text{ a}$  a VOC destruction results of about 700 ppt h<sup>-1</sup>. When this fraction is projected over a period of 5 hours, similar to the CH<sub>4</sub> transformation, a depletion of about 3500 ppt is obtained. PAULSON AND SEINFELD [1992] calculate a CO yield from isoprene oxidation to be in the order of 3.4 CO per molecule of isoprene, which leads to a CO formation of about 11.9 ppb. However, one has to take into account that the reaction is limited by the replenishment of VOCs, i.e. the total CO formation will decrease with time. Nevertheless, by the consumption of the pool, which takes about 1 hour of time, 2.4 ppb CO will be formed, that is approximately 40 % of the observed 5.9 ppb.

When using CO as a tracer for CO<sub>2</sub> formed by combustion processes to identify particularly anthropogenic contributions, a determination of the individual sources of CO is mandatory. If conversion from CH<sub>4</sub> and VOCs is neglected, which

contribution to CO formation can be assumed to be in sum about 60 to 100 % at the Florarna site, an overestimation of CO<sub>2</sub> input from anthropogenic sources seems to be quite probable. However, a probable affection by advection becomes again evident, because conversion can not explain solely the observed changes of the CH<sub>4</sub> mixing ratio.

Since CO formation happens from manifold sources via several reactions and with variable formation efficiencies [NOVELLI et al. 1998, WOTAWA et al. 2001], a realistic identification and assessment of different sources is not achievable with the current equipment. It would, therefore, a desirable improvement to implement continuous CO recordings and, if possible, to include situ measurements of VOCs and OH into the analytic scheme.

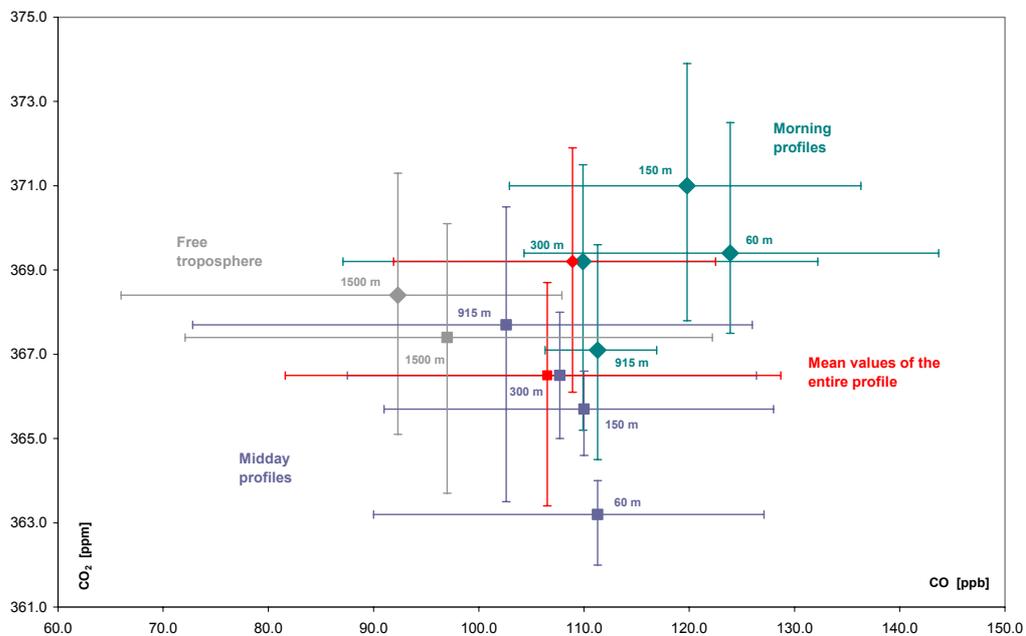

**Figure 5.17.** Mean mixing ratios of CO<sub>2</sub> and CO from each flight level (excluding 60 m morning flight height, as mentioned in figure 5.9.) and means of the entire profiles from flights above the *Florarna* ground reference sites on 29 and 30 August and 1 September 2001 (Upland / Sweden). Morning results are shown as solid diamonds, midday data as solid squares. The bars for CO<sub>2</sub> and CO indicate the range of the mixing ratios throughout all days. For comparison with results from the Hainich study area see also figure 5.18.

It also has to be taken into account that CO itself is a precursor, since it is oxidised by OH to CO<sub>2</sub> (see reaction formula 2.1.2.1.). Regarding the amount of carbon derived by this way from global estimates (see table 2.1.) a contribution in the order of 0.6 – 1.1 PgC/a has to be expected, i.e. a fraction of 0.5 – 0.9 % related to

the postulated C flux between land and atmosphere of about 120 PgC/a [HOUGHTON et al. 2001].

Contrary to the conversion reaction described for CH<sub>4</sub>, the mixing ratio of CO is not higher than the formation product, but much smaller than that of CO<sub>2</sub>. Thus, significance with respect to an increase of the CO<sub>2</sub> mixing ratio seems unlikely. From a calculation (with CO = 120 ppb,  $k = 2.4 \cdot 10^{-13} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$  [WARNECK 2000] and  $\text{OH}_{\text{conc.}} = 1 \cdot 10^7 \text{ mol cm}^{-3}$ ) results a CO<sub>2</sub> yield of 1 ppb h<sup>-1</sup>, i.e. 5 ppb during 5 hours observation period. Based on the observed depletion this additional input would effect a minor underestimation of the CO<sub>2</sub> flux; the difference between a calculated surface flux including the supplementary CO<sub>2</sub> yield and the one unaccounted for this affection is in the order of 2 %.

**Figure 5.18.** Mean mixing ratios of CO<sub>2</sub> and CO from each flight level and means of the entire profiles from flights above the Hainich study site within the SPA<sup>13</sup>CE experiment on 6, 14 and 15 August 2002 (Thuringia / Germany). Morning results are shown as solid diamonds, midday data as solid squares. The range of the mixing ratios covering all days is indicated by the bars for CO<sub>2</sub> and CO.

### ***APPLICABILITY OF THE 'CBL-BUDGET APPROACH'***

From the analysis of the flight data it becomes obvious that fundamental assumptions of the 'CBL budget approach' (like linearity, see chapter 2.1.3.) are most frequently not prevalent.

The 'CBL budget approach' is based on the hypothesis that the changes within the observed air column are completely explainable by the monitored fluxes. The influence of the subsidence should thereby be calculated from meteorological observations, or rather from results of reanalyses obtained from NCEP (National Centers for Environmental Predictions; USA). Furthermore, the contribution of entrainment should be assessable by the definition of individual CBL top heights for each profile. The heights are estimated from the curves of the potential temperature  $\theta$  and the relative air humidity  $f$ , respectively, and the specific humidity  $q$ . Finally, it is assumed that horizontal advection is negligible.

From the field observations it has turned out that in particular the last two assumptions are not met. It was frequently not possible to determine the CBL top height from the profile data of  $\theta$  and  $f$  (see figure 5.19.).

The fact that the CBL column is mainly affected by horizontal advection became obvious by the observed high temporal variability of the non-active trace gas mixing ratios. That the conditions of the 'region' are much more affected by large scale influences than expected is indicated by the random shift of the trace gas composition observed even in the free troposphere, which should also be used as background reference.

Another crucial error assumption became obvious by the high variability of the mixing ratios on small spatial scales and by the occurrence of stable stratification within the CBL. On average, the CBL is mixed less efficiently by convective processes than expected (see chapter 4.2.3.8. and figure 5.19).

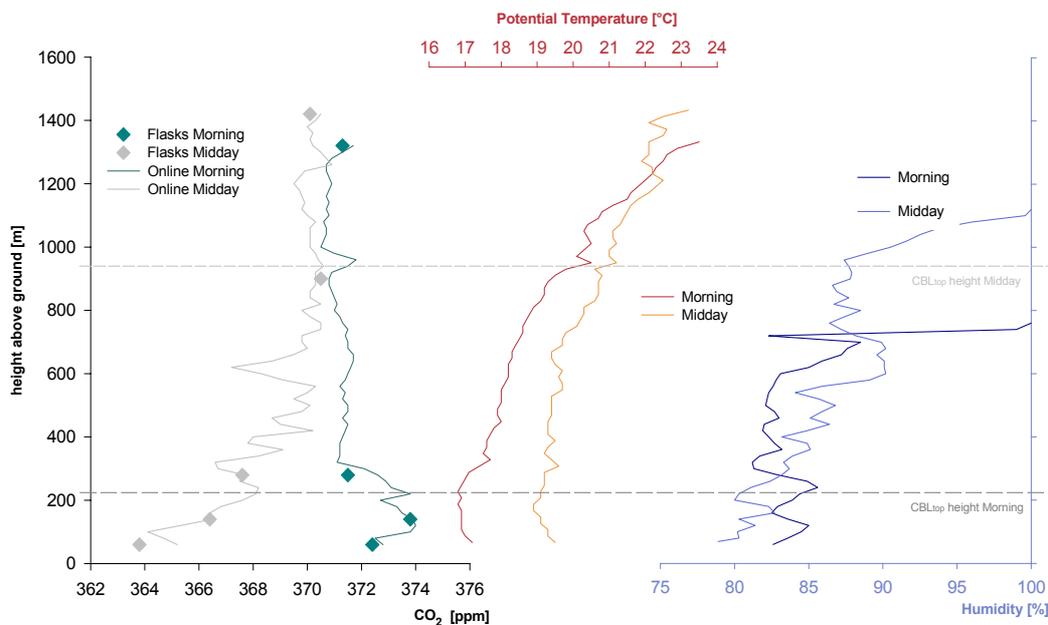

Likewise in this context, an additional uncertainty is caused by the temporal inconsistency of the transported air with respect to the direction and the speed at the individual levels. Thus, 3D field descriptions of the mixing ratios and the wind speed are needed in order to calculate properly the entrainment and the budget [VILÁ-GUERAU DE ARELLANO et al. 2004].

Related to these findings it turned out that profiles performed above only a single site were not able to provide representative data for the entire study region (→ The Netherlands field campaigns, chapters 4.2.6. & 4.2.7.).

When using the ‘fixed-mass’ budgeting approach (which neglects horizontal advection), LAUBACH & FRITSCH [2002] have quoted the error estimates to be 10-20% for CO<sub>2</sub>. In fact the margin of error resulting from the interferences might be in the same order of magnitude than the expected signal from the processes that should be quantified - or even exceeds this. In particular, the rapid replacement of local air by air masses of quite different origin prevents regional flux- and budget estimations. In one case the probable error resulting from day-to-day variability due to advection (14 to 15 August 2002, SPA<sup>13</sup>CE experiment) is assumed to be approximately 50% of the expected diurnal cycle.

Because of stratification, with mixing ratio differences several magnitudes higher than the value of the expected diurnal depletion, no realistic estimation of the error potential of this source can be given. On the other hand, exemplified by the flight on 15 August 2002, a range up to 130% might be not unrealistic.

As expected, the sum of all errors make useful estimates unacceptable.

**Figure 5.19.** Profiles of potential temperature, relative humidity and CO<sub>2</sub> mixing ratios obtained from Licor online measurements and flask samplings. Shown are also the CBL<sub>top</sub> heights derived from the profiles of  $\theta$  and  $f$ . Flights were performed above the *Hainich* around 8:00 and 12:30 UTC on 14 August 2002.

### 5.3. Summary of Methodological Experiences

Multiple tracer analyses emerged to be an important approach regarding carbon investigations in the lower troposphere. Compared with previous CBL studies, mandatory information for the characterisation of the sampled air became available by implementing multiple tracer comparison examinations. Thus, for this study basic information could be obtained with respect to the verification of the underlying theories and the practised strategies, in particular the identification of most critical impairments. The multiple tracer analyses were also essential for the interpretation of the data regarding the characterisation and comparison of the RECAB study regions.

As a basic finding it should be noted: Which *spatial* and *temporal* character is represented by the air of the individual flasks is definitively determined by the instantaneously prevalent conditions of the sampled volume. Thus the '*where and when*' of the sampling has a major influence on the results of the budget calculation.

Systematic errors caused by the sampling unit were minimised by the development of a new construction scheme (see chapters 3.2. ff.). By the establishment of a ground reference unit additional information became available regarding the identification of affecting impairments (discussed in the following chapter 5.4). Regarding the characterisation of the sampled air, fundamental information has been obtained by comparison- and correlation-studies focussing on the trace gas composition and the delta<sup>13</sup>C fraction. Benefit with respect to the effects caused by advection could also be achieved from the combined approaches with modelling studies.

Diverse sources of uncertainty could be identified by the multiple tracer analyses. But most importantly, a quantification of the disturbing potentials could not be achieved because of the low amount of data.

However, by the examination of data from the field experiments some calculations were performed, which give at least an impression regarding the magnitude of uncertainty. Variability in the order of ~50% regarding the expected diurnal effect by assimilation uptake due to the affection by advection was described for the

SPA<sup>13</sup>CE experiment (p 103ff.). Because of improper definition of the CBL<sub>top</sub> height, flux discrepancies of about 8% were pointed out from the summer campaign in The Netherlands (p 99f.). Provoked by time delayed detection of the signals due to transport processes, a difference of ~ 40% between observed and notional values was calculated (p 134f.). The error potential due to stratification, exemplified by summer time profiles taken above the Hainich, was in the order of ~50% (p 106ff.). Another process, affecting primarily the CO<sub>2</sub> / CO ratio used as one parameter to determine the contribution of anthropogenic sources to the CO<sub>2</sub> signal, was analysed on data basis from the Swedish experiment. Due to conversion processes arose an uncertainty with respect to the CO fraction of about 60 – 100% (p 135ff.). LAUBACH & FRITSCH quote the error estimate for CO<sub>2</sub> to be 10 – 20% when using their 'fixed mass approach'; neglecting all of the listed processes above except the uncertainty from the determination of the CBL<sub>top</sub> height. Finally, there are more processes whose contribution could not be sufficiently estimated, like the affection by contaminations (see for instance chapter 4.2.1., p 80).

As a corollary with respect to the applicability of the 'CBL-budget concept' it has to be concluded that several fundamental parameters could not be determined as precisely as necessary. In addition to this, uncertainties were caused by temporal and spatial inconsistencies (see chapter 5.2.). As a result it appears that the common experimental strategy based on the 'CBL-budget approach' does not seem to be optimal for estimating the carbon balance on a regional scale.

As a consequence a new sampling strategy was developed whose design considers critical impairments like advection, alteration and local effects (discussed in detail in chapter 5.4.). However, the capability of the enhanced examination scheme could not finally be determined because of technical problems and insufficient equipment.

## IDENTIFIED IMPAIRMENTS

### Application of regional 'CBL Budgeting Studies' – Spatial and temporal aspects

- *mismatching of scales and 'regional rectifier'*: The extension of the represented area, which is defined by the height of the well mixed CBL, does not match the spatial extension of the 'region' to be studied. Additionally, the CBL height is highly variable, which depends mainly on solar irradiance. As a consequence to this, the extension of the study region is also not constant. A well developed CBL may provide information even from continental scales in summertime, whereas a shallow winter CBL will reflect rather local contributions. (Chapters 4.2.3.1., p 84ff., 5.2., p 127ff.)
- *air mass exchange / background shift*: Significant modifications of the gas composition are caused by advection. Advection is, therefore, one dominant parameter which affects to large extent the calculation. In consequence: a reliable quantification of the carbon balance was impossible to achieve by using the available equipment. (Chapters 4.2.6.,p 95ff., 4.2.8.1., p 102ff., 5.2., p 127ff.)
- *small scale variability*: The high variability of the tracer mixing ratios, effected by various source and sink types and activity, as well as insufficient turbulent mixing, provokes distinct differences on small scales (horizontal, as well as vertical stratification) which are a main source of uncertainty with respect to the sampling strategy, the data interpretation and the budgeting. (Chapter 3.1.2., p 43ff.)
- *turbulent mixing*: Because of the most frequently observed insufficient turbulence within the CBL, the development of a 'regional average mix' was not achieved. Instead, the establishment and persistence of stratification was recorded quite often. (Chapter 4.2.8.1., p 105ff.)
- *wind profile inconsistency*: Highly variable temporal and spatial conditions of wind direction and velocity were observed. Which means that exchange processes might occur rapidly, separately and independent at the

individual profile layers. From the analysis data provided by the weather services this behaviour can not be estimated sufficiently.

(Chapter 4.1.5., p 70f.)

- *contaminations:* Particularly in cases of insufficient turbulent mixing contaminations from local sources may affect the measurements in a serious way. Even in the free troposphere pollution plumes could be observed.

(Chapters 3.1.2., p 44ff., 4.2.3.1., p 84ff., 5.1.1., p 113ff.)

- *conversion:* Possible modifications of the CO / CO<sub>2</sub> ratios due to conversion reactions (CH<sub>4</sub>, VOCs), which can not be verified with the available equipment.

(Chapter 5.2., p 135ff.)

- *determination of the CBL top height:* The proper determination of the CBL height, which is necessary for the budget and flux calculations, is frequently not possible from the available measurement data. Since it can be assumed that the CBL top is not a plain structure, a determination by solely vertical profiles is critical. Additional investigations by soundings will offer a suitable solution.

(Chapters 4.2.7., p 100ff., 5.2., p 141ff.)

- *lack of basic information:* Pre-flight information about the CBL structure for the determination of the sampling heights, with respect to the occurrence of distinct different layers, was not available.

### Data Potential

- *data quantity:* The flight studies provided only a limited number of data. Because of the observed high variability and the missing of real replications of the measurements, the quantity of the data sets is not sufficient for reliable characterisations of the study site, nor for an estimate regarding the representation capability of the data for the studied region.

It also has to be taken into account that the CO<sub>2</sub> flux is no linear process but an effect of complex interactions, for instance the relationship of ambient CO<sub>2</sub> mixing ratio, temperature and vapour pressure, irradiance for the carbon uptake by assimilation.

(Chapter 2.1.4., p 28ff.)

- *insufficient number of observed parameters:* Lack of observed parameters, like the 3-dimensional wind field (with needed high resolution regarding the small scale variability) and the absence of continuous measurements of additional trace gas species (in particular CO). This information would at least be necessary for back tracking investigations regarding the source identification and for the data interpretation in general.
- *not comparable environmental conditions:* Since the experiments could not be executed concurrently and under similar conditions (for example the weather situation, the status of the vegetation, the day length) these basic uncertainties have to be taken into account regarding a direct comparison.
- *unrepresentative conditions:* Frequently, the campaigns were performed under environmental conditions, which were not characteristic for a long year average ('The Netherlands' winter experiment, 'Italy' summer campaign).

#### Technical Conditions

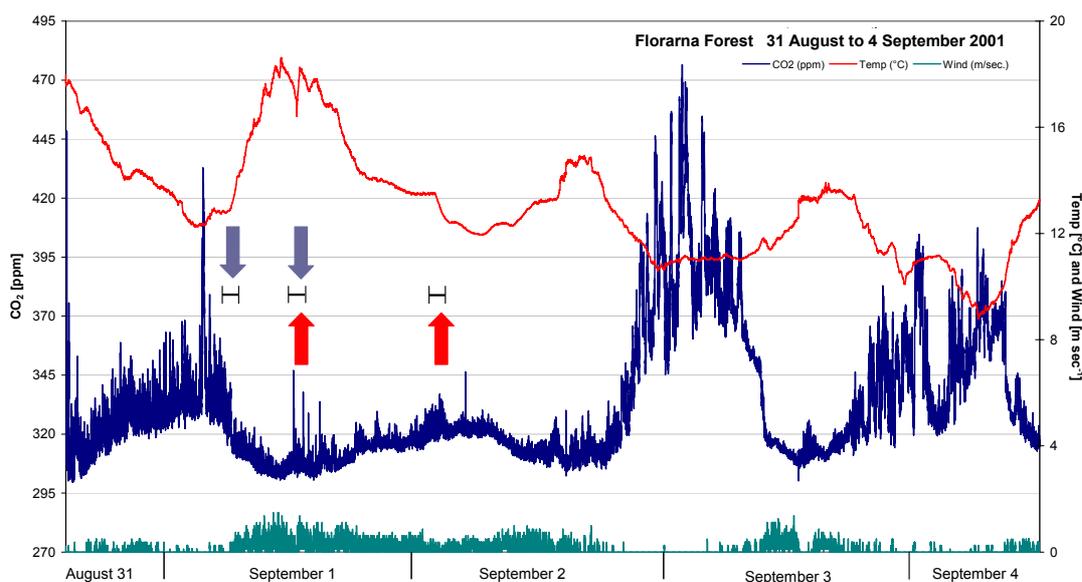

- *sampling and measurement instrumentation:* Problems due to the affections caused by the chemical drying reagent on H<sub>2</sub> continue to exist, as well as investigations with respect to probable interferences on the delta<sup>18</sup>O ratios, and a mismatch of the online CO<sub>2</sub> mixing ratio data with laboratory measurements.
- *performance of the flight operation:* Due to the required weather conditions and because of aviation regulations, sampling flights can only be performed during limited time frames and within specific areas.

## 5.4. Enhanced Investigation Strategy

From the observations it became obvious that the dynamical behaviour of the CBL and its structure are frequently not developed as expected. A corollary of the observations was that further examinations had to verify the basic assumptions with respect to their validity. Following these findings the investigation concept was modified by a) the regular implementation of ground reference measurements and sampling and b) by the adaptation of the flight strategy.

### 5.4.1. Implementation of Ground Reference Measurements and Sampling

In contrast to the practised scheme, the establishment of an independent reference seemed to be imperative in order to carry out the flight measurements as more or less self-contained studies. Additionally, a more specific estimation of the contribution from local surface processes seemed to be mandatory.

**Figure 5.20.** Continuous measurement records taken at the wooded site within the *Florana* nature reserve (Uppland / Sweden) by the mobile ground reference unit from late afternoon on 31 August 2001 [16:00 UTC] until midday on 4 September 2001 [11:30 UTC]. Indicated by the black bars are periods when flask sampling were performed simultaneously ; blue arrows specify flight sampling events, red arrows specify near surface samplings respectively.

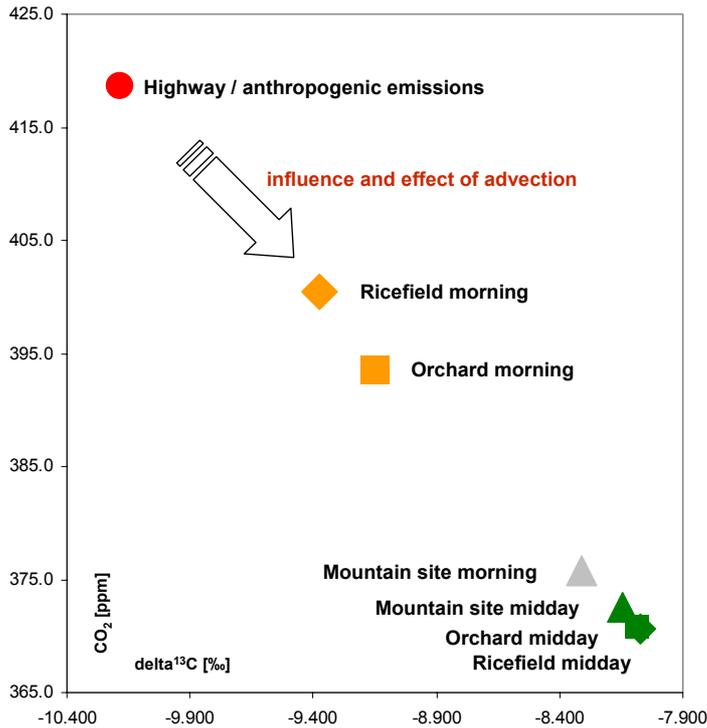

For this reason the ground reference unit was developed, recording continuously meteorological and eco-physical parameter, as well as the CO<sub>2</sub> mixing ratio and to provide the opportunity of flask sampling (for system description see 2.2.1.3., Appendix A2 and the documentation folder on the CD-ROM). A major requirement

for the construction was to obtain a low-cost system designed for the autonomous utilisation even in unapproachable terrain. A configuration was established that can be, in case of need, handled by only one person. Because of its low cost, several systems might be integrated in the investigation scheme observing different profile sites concurrently.

The aim of this construction was to associate the flight data with the activity of the regional ecosystems. Figure 5.20 presents data obtained by the ground reference system at a remote site in Sweden. Indicated are, beside the records of CO<sub>2</sub> mixing ratio, air temperature and wind speed, the periods when profile flights and ground reference samples were taken. The graphs clearly show the relevance of the environmental conditions and the ecosystem behaviour. For instance, the carbon uptake is not a linear but quite a complex process. The efficiency of the uptake depends inter alia on the ambient CO<sub>2</sub> mixing ratio, temperature and vapour pressure, the amount of the photosynthetic active radiation (PAR), etc. (see chapter 2.1.4., p 28f.).

Another example with respect to the benefit of the additional information is presented in figure 5.21. The results shown are from the winter campaign in Spain, illustrating the range of the observed differences regarding the CO<sub>2</sub> mixing ratio and the related delta <sup>13</sup>C values: on the one hand the anthropogenic contributions are obvious, when comparing the results from the sampling next to the highway with the samples originating from the remote mountain field site. On the other hand, the influence of advection can be recognized from the night time <sup>13</sup>C signal observed at the rice field site and within the orchard.

Caused by a land-sea-wind circulation, contaminated air from the highway and the urban settlements was transported by offshore winds to the orchard and the rice field site. Chapter 5.2. 'Variability – Air Mass Change' focus mainly on the flight results. A detailed description of the exchange scheme is given in figures 9 and 10 in the documentation folder on the CD-ROM.

**Figure 5.21.**

Characteristic signatures of different land use classes, i.e. CO<sub>2</sub> sinks and sources (Valencia / Spain; December 2001). The effect of advection is indicated by the night time data from the rice field and the orchard (plant) site – which are reflecting in fact a *mixed* signal with main contributions originating from anthropogenic sources.

The experiments presented in chapters 3.2. (p 48ff.) and 4.2.2. (p 81f.) showed, that both sample systems, the modified flight sampling system and the ground reference unit, are compatible, which is a basic need regarding the real linkage of the flight profiles to the surface processes we are interested in.

Due to the importance of the data obtained by the ground reference system it is an integral feature within the 'Transect approach'.

#### 5.4.2 Adapted Flight Investigation Strategy – ‘Transect Approach’

As could be shown in the previous sections the applicability of the CBL-budget concept is subject to a high potential of uncertainty, primarily due to environmental conditions like advection and the mixing status of the boundary layer (see chapters 5.2. and 5.3.). Adjustments, for instance the implementation of a footprint (*‘Transportfunktion’*) feature for the vicinity of the sample location, as discussed by FRITSCH [2003], will fail, since the effective processes are still missed. The utilization of eddy-correlation data from local tower measurements, for calibration and quality control, provides only an apparent reference because these observations are also affected by the processes which shall be excluded (see findings from the SPA<sup>13</sup>CE experiment, chapter 4.2.8.).

The limitation due to the required environmental conditions is also a problem that affects the applicability of Lagrangian attempts. As described for example by SCHMITGEN et al [2004] the experiment performed in the ‘Landes des Gascogne’ region (France) was designed as a quasi ‘one-process-orientated’ study, focussing on the CO<sub>2</sub> uptake by a forest. The premise for detecting a significant decrease of the CO<sub>2</sub> mixing ratio due to the uptake by assimilation is the ability to persecute an air mass for a period above a certain land surface. Thus the practicability is bound to dedicated regions, and to definite weather conditions – which were prevalent only at one of four flight days during the experiment.

As a conclusion one has to challenge to what extent results from both approaches, biased to exceptional situations, can reflect a representative character of a region.

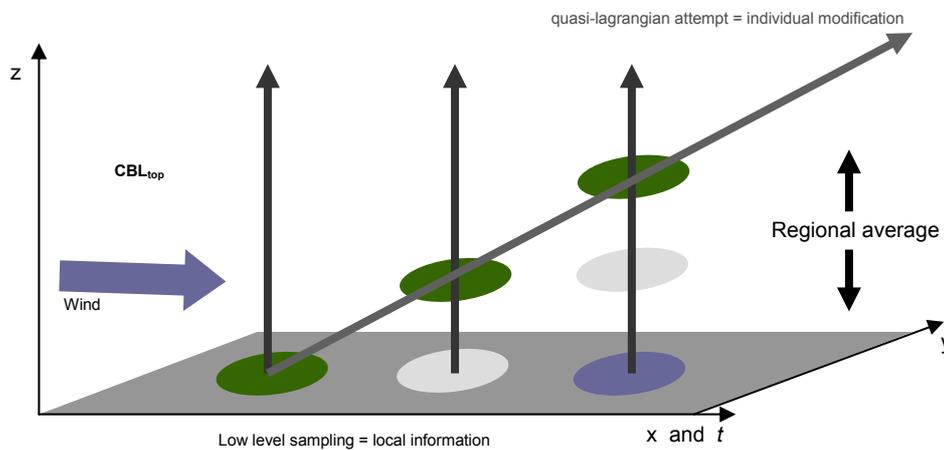

In consequence, with the ‘Transect approach’ an improved investigation concept was developed which takes the most important impairments into account.

The idea is based on the sampling of vertical profiles, above the most representative land classes during each flight, but also taking advection and further forced modifications of the air within the ‘regional’ scaled column into consideration. Thus the results should be obtained from a combination of

- a) the local source and sink activity, derived from the lowest level samplings,
- b) the ‘regional’ average from the samples taken through the entire profile
- c) a ‘quasi-Lagrangian’ attempt to assess the individual modifications.

- d) Additionally ground level reference investigations with flask sampling, continuously CO<sub>2</sub> measurements and recording of meteorological and eco-physical parameter aiming the linkage to the surface processes.

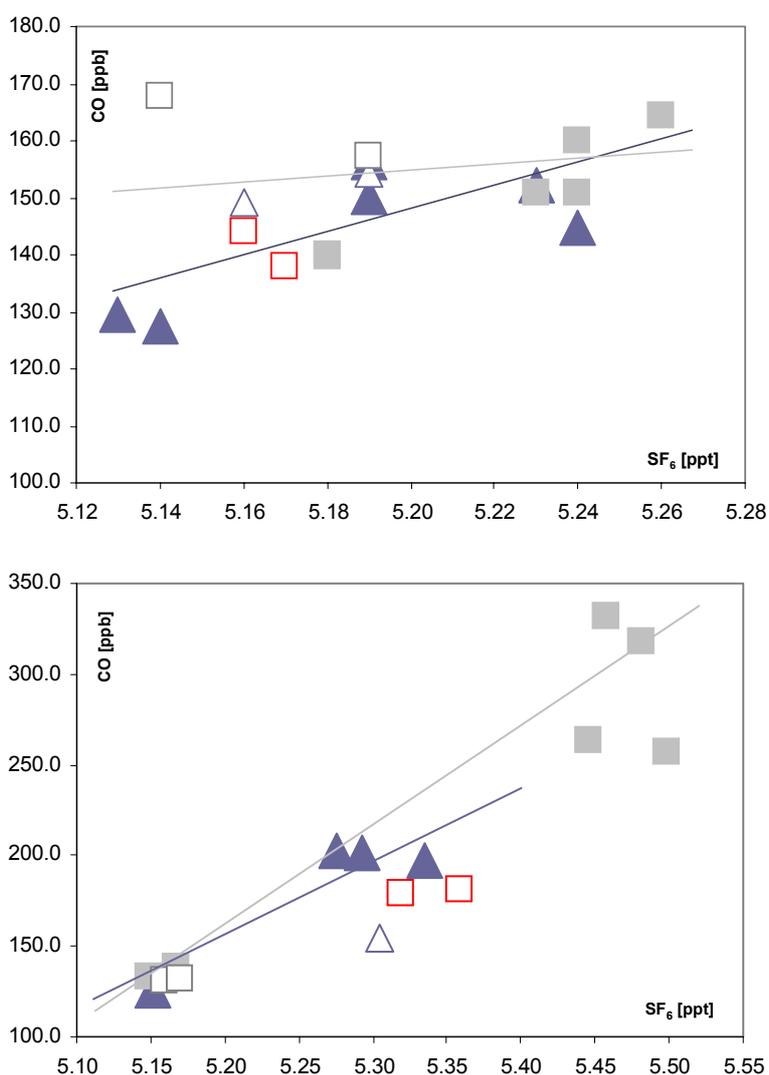

The hypothesis is that a regional representative can be obtained from a combination of successively executed profiles at multiple characteristic locations along a line of the prevailing wind direction, with a 'chronosequence' of these individual source signals. Thus the intention of taking the advection explicitly into account was to minimize the random background shift at the profile sites and to get information about changes caused by other modifying processes.

**Figure 5.22.** Scheme of the 'Transect Approach'. The profile sampling follows the stretch of the wind. Sampling is performed above various typical land use classes: local information will be obtained from the low level samples, as well as from additional ground level reference investigations. At the following profile sites the ground signal should be found again at higher altitudes but already with a modified character (quasi-Lagrangian attempt). By the entire profile at the end of the transect the regional average should be represented. An estimation of the diurnal effects and of affections from advection has to be achieved from the results of the replicated flights during the day.

Another aim was to assess and minimise the uncertainties that are caused by the environmental conditions. Even if there is still no direct information available to estimate the amounts entering the investigation column, a significant enhancement might be achievable when implementing a 'semi Lagrangian' monitoring attempt. Thus the attempt of the 'transect approach' can be seen as a fusion of the originally intended Eulerian consideration with a simple Lagrangian treatment.

Figure 5.2. represents the relationships of CO and SF<sub>6</sub> data obtained from flask sampling within the CBL during the Dutch summer experiment. Displayed are the results of the morning flights performed above the most western site (Cabauw, marshland – blue triangles) and the more easterly location (Maize – greyish squares) and by the red outlined squares the midday results from the 900m sampling level. On 16 July 2002 north-west winds occurred, on 27 July 2002 south westerly wind direction was dominant.

**Figure 5.8.**

Relationship of CO and SF<sub>6</sub> mixing ratios from flask sampling performed during the summer campaign in The Netherlands on 16 July (upper panel) and 27 July 2002 (lower panel).

Displayed are data from the morning flights within the CBL above the *Cabauw* (blue triangles) and at the *Maize* location (grey squares). By the red outlined squares the results from the midday sampling at the 900m level at the *Maize* site are indicated. The 900m samples from the morning flights are also shown by outlined symbols. Linear fits through the data points are applied

When analysing the results from the morning profiles at both locations with regard to an attribution of the maize midday data, it becomes obvious that a better correlation with the character of the air identified in the morning at the Cabauw site, than with the air sampled in the morning at the maize site, is present. This

observation suggests that the intended following of a local signal could be achieved.

Associated with the investigation strategy was the application of the modified flight sampling unit. In this context the most important enhancement has to be seen in the operation mode, to flush and sample under final pressure combined with an adjustable flow rate. Adapted to the aircraft speed 'average way lengths' for the flask samples can be defined. With a flight speed above ground of 140 km/h and a sampling flow rate of 3 l min<sup>-1</sup> the passed distance during the period the volume of a flask exchanges once is about 1600 m. Since the two flasks are arranged in line one can obtain two individual samplings representing each 1600 m, which combined averages a way length of about 3200 m. Additional information is provided by the comparison of the individual flasks, since the differences reflect the presence of small scale variability. However, one might obtain *ex poste* a rough impression of the amount – but an estimation regarding the scales of the variability is still unsolved.

#### UNCERTAINTIES

Also this examination concept is still forced by restrictions, as could be derived from the flights performed in The Netherlands (see chapters 4.2.6. and 4.2.7.). Air mass changes in particular may affect the sampling, caused by the variability of the wind direction and an associated probable lateral advection. Also the definition of the transect basics, for example its orientation, is difficult especially in highly urbanized areas.

Where and when to sample are most crucial decisions, determining the results. To accommodate this uncertainty pre-sampling information regarding the scale of variability should be obtained by in-flight high frequency measurements. Further improvements are needed, like the documentation of the CBL structure which also has relevance regarding the requested additional information for the model calculations.

## 6. CONCLUSIONS

This study has demonstrated the appropriateness of multiple tracer analyses and proposed an enhanced investigation strategy that overcomes the highlighted impairments of previous approaches. Further, this study has also established the validity of using multiple tracer analyses for the study of the carbon cycle. It turned out that multiple tracer analyses are not only an adequate tool – but that multiple tracer analyses are of rather basic importance for investigations focussing on the carbon cycle.

### 6.1. Relevance of the Results

The budgeting of dynamic systems implies in principle great uncertainties. It becomes in particular problematic when assumptions turn out to be unrealistic and fundamental parameter can not be determined sufficiently. In this study problems with respect to regional carbon budgets are identified, caused by complex interactions of different processes. Frequently, inefficient vertical mixing is accompanied by rapid horizontal air mass changes. Due to the relation between transport distance and time the simultaneous occurrence of air originating even from opposite formations is not uncommon. On account of this, one finds in the CBL large temporal and spatial variability on a small scale. Thus the '*where and when*' of the measurements is a crucial parameter. Further, since the flows entering and leaving the '*CBL column*' can not be determined properly, a demarcation of the spatial unit '*region*' is difficult. Due to these impairments regional budgets from profile flights are prevalently impossible.

Also, surface observations are subject to the effects described for the airborne investigations. By linking the flight sampling to near surface measurements it was proven that changes caused by advection and entrainment are effective through the entire profile. When the relationship between transport velocity and kinetic of the surface-atmosphere interactions, defined by Taylor's hypothesis, are exceeded, or when air mass change occurs by vertical transport, a rapid alteration of the footprint from local to larger scales is unavoidable.

By combining modelling studies with the results from multiple tracer analyses, mutual benefit can be obtained. Transport models provide helpful information for the identification of most probable source regions. On the other hand, these field measurements provide data which help to validate processes simulated in the models.

## **6.2. Perspectives**

Benefits were obtained by enhancements focussing on sampling system and investigation strategy. However, the linking between local investigations and continental studies could not be achieved. But, highly accurate information with respect to the *actual local* situation became available by flask sampling combined with continuous measurements. Thus, the goal of advanced studies should be a catenation with continuous near surface multiple tracer analyses. Most suitable might be a combined approach of tall tower and airborne studies. Benefits from the airborne investigations will be obtained through aircraft mobility, in particular from sampling the 'dynamic background' within the free troposphere, and from additional samplings at several distributed locations within and outside the tower's footprint area, realising the new *transect approach* sampling strategy.

A major problem of the RECAB project was the study area itself. Because of its heterogeneity the appearance of processes was quite complex. But knowledge about these conditions is mandatory for an application.

Thus, when go on to scale up source regions, a simple study area, i.e. a more homogeneous landscape, has to be chosen. And, before trying to get a budget number, more basic information has to be obtained: It became obvious that the structure and dynamics of the lower atmosphere are not understood well enough for such calculations. Regarding the occurrence of stratification, as well as for the study of the CBL dynamic in general, the implementation of 3-dimensional high frequency wind field measurements is mandatory. Further enhancements should be achieved by additional ground-based soundings (SODAR) for the description of the CBL top height.

Large homogeneous regions like Siberia are of particular interest, because in northern boreal regions with wetland areas and permafrost soils two highly sensitive land classes are dominant where, due to the anticipated climatic changes, additionally CH<sub>4</sub> and CO<sub>2</sub> contributions have to be expected. Additionally, the conversion of CH<sub>4</sub> and VOC has to be taken into account, since an estimation of CO formation is a basic requirement when using CO as tracer for combustion derived CO<sub>2</sub>.

In order to meet the requirements for such investigations, an enhanced instrumentation and additional continuous profile measurements of an advanced gas spectrum (CO, CH<sub>4</sub>, OH and stable isotopes in CO<sub>2</sub>; by gas chromatography and tuneable-diode-laser-mass spectroscopy) are necessary. With respect to a division of contributions from fossil fuel consumption and biomass burning it is desirable to analyse individual air samples also for <sup>14</sup>C.

Finally, modelling approaches should be an integrative part of the studies. On the one hand, forecast models should be used to facilitate the setup of the experiments. And on the other hand, information about transport and transformation processes need to be modelled to narrow down possible source areas.

Than are dreamt of in your philosophy.'*

*HAMLET ACT I, SCENE 5*

## 7. SUMMARY

Great capability was ascribed in this study to multiple tracer analyses as a tool for the interpretation and characterisation of air samples. The potential and capability of multiple tracer analyses was examined by focussing on processes and environmental conditions, based on data obtained from air sampling performed within the EU project RECAB (Regional assessment and modelling of the carbon balance in Europe). The motivation for the study was the need to close the gap between local and continental/global scales.

Because of the significance of the observations particular focus was given to the experimental investigations. Due to the findings of prior test flights and from results obtained by the RECAB field campaigns, specific laboratory experiments were carried out to evaluate the appropriateness of the 'CBL-budget approach', that was proposed for the estimations of the regional carbon budgets.

Since the campaigns provided on the one hand data from the regular profile flights, but were used on the other hand for enhanced experiments and validation studies, the observations and the interpretation of the results are pointed out more explicitly.

From field data and specific laboratory experiments, severe impairments were identified, regarding the appropriateness of the technical equipment and the validity of fundamental assumptions about the CBL behaviour.

It was found that basic assumptions of the current strategy did not reflect the real conditions, primarily because of insufficient perception about the dynamics and the structure of the CBL.

Additionally, it turned out that with the 'up scaling', besides the extension of the spatial aspect – from the leaf level to the region, an importance is attributed to the complex interactions of spatial and temporal processes. A change of the spatial scale is directly connected to an adjustment of the time factor and vice versa. With this in mind, the coupled factors of horizontal advection and entrainment have to be mentioned. This also includes air from the free troposphere, as well as the influence of gas phase reactions with respect to the trace gas composition of the air samples.

Because of the identified impairments, the aim of the RECAB project – The qualification and quantification of carbon budgets within regions – could not be achieved as desired. Instead, mandatory requirements to improve investigations were specified and initiated: e.g. a new configured system for flask sampling, a ground reference unit were designed, and an enhanced investigation strategy was developed, focussing on flight and ground level studies.

Concluding the findings their relevance and their transformability to related studies have been evaluated. Finally, the requirements and potential foci for advancement measurements were discussed, which should perform the enhanced investigation strategy combined with ground-based continuous multiple tracer analyses.

## A2 EQUIPMENT

### Instrument Description – Configuration of sampling units

Flight sampling unit: ½“ Decabon<sup>®</sup> tube (length 650 cm) from wing tip to pump (KNF N 145.1.2.AVE) – ¼“ steel tube outlet – 3-way-valve (Swagelok; 1 – pump out, 2 – sample unit, 3 – cockpit) – ¼“ Decabon<sup>®</sup> tube (all lines within the sample unit) - coalescing filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GE-15K-FC-03]) – massflow controller (Bronkhorst F201C-FAC322-V [flushing rate ~10.5 l min<sup>-1</sup>, sampling rate 3.0 l min<sup>-1</sup> at 2 bar abs.]) – vertical drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 70 g] as binder medium (Fluka Chemika) – particle filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GS-15K-FC-03]) – unidirectional restrictor valve (Swagelok) - mechanical flow controller (only for control purpose, Krohne 0/232939.2) – 3-way-valve (Swagelok; 1 – in, 2 – out →sample unit, 3 – out →restriction outlet 1 bar rel. [Swagelok RL4 (0.7-15bar)]) – analog manometer (Empeo, NR63.14 0-2.5 bar) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½“ Cajon Ultratorr shafts (Swagelok) – pressure controller (Bronkhorst P702C-FAC-22-V; restriction 2 bar abs.)

Original flight sampling unit: ½“ Teflon<sup>®</sup> tube (length 650 cm) from wing tip to horizontal drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 65 g] as binder medium (Fluka Chemika) – ¼“ Teflon<sup>®</sup> tube (all lines within the sample unit) – particle filter (Gelman, 1.0 micron) – pump (KNF N 814 KNDC) – unidirectional restrictor valve (Swagelok) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½“ Cajon Ultratorr shafts (Swagelok) – 3-way-valve (Swagelok; 1 – in, 2 – out →flushing, 3 – out →sampling); *for flushing:* – mechanical flow controller (Krohne 0/232939.2) – outlet *for sampling:* – analog manometer (Empeo, NR63.14 0-2.5 bar) – restriction outlet 2 bar abs (TAVCO, 2391244-8-3)

Ground sampling unit: ½“ Decabon<sup>®</sup> tube from mast to pump unit (two pumps in row: KNF N 828 KNDC & KNF N 814 KNDC) – ¼“ Decabon<sup>®</sup> tube (all lines within the sample unit) – horizontal drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 65 g] as binder medium (Fluka Chemika) – particle filter (Gelman, 0.3 micron) – mechanical flow controller (Krohne 0/232939.2) – unidirectional restrictor valve (Swagelok) – analog manometer (Empeo, NR63.14 0-2.5 bar) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½“ Cajon Ultratorr shafts (Swagelok) – restriction outlet 1 bar rel. (Swagelok RL4 (0.7-15bar))

### A3 Configuration of analytical instrumentation

Gas Chromatograph [GC]: flasks with sampled air connected with Cajon Ultratorr fittings to  $1/16$ " stainless steel capillaries – drying tube ( $1/4$ " , 2 g  $Mg(ClO_4)_2$ ) – sample standard selection valve (8 Port Valco multiposition valve: EMTCS8UWE) –

*GAU1 (FID for  $CH_4$  and  $CO_2$ ,  $ECD_1$  for  $N_2O$ ):*

linked to first GC injection valves [**FID line**]: Valco two-position valve (ET6C10UWE) – flushing sample loops FID 2.2 ml – connected via sample loop separation valve (ET6C4UWE) to second GC injection valve [ **$ECD_1$  line**] (ET6C10UWE) – ECD sample loop: 5 ml – sample flow rate regulated by mass flow controller (MKS 1179A) - GC columns (FID/ECD): Hayesep Q 6 ft x  $1/8$ " (pre-col) and Porapak Q 12 ft x  $1/8$ " (main col) - ECD line: methanizer bypass valve (EHC4WE) – methanizer (Agilent Nickel Catalyst Assembly Part No G1580-61020) – ECD  
FID line: FID

*GAU2 (RGA for CO and  $H_2$ ,  $ECD_2$  for  $SF_6$ ):*

Linked to first GC injection valve [**RGA line**] (ET6C10UWE) – flushing sample loop RGA 1 ml – connected to second GC injection valve [ **$ECD_2$  line**] (ET6C10UWE) – ECD sample loop 25 ml – sample flow rate regulated by mass flow controller (MKS 1179A) - GC columns (RGA): 3 ft x  $1/8$ " glass beads , 3 ft x  $1/8$ " molecular sieve - RGA; GC columns ( $ECD_2$ ): Hayesep Q 6 ft x  $3/16$ " (pre-col) and Hayesep Q 10 ft x  $3/16$ " (main col) -  $ECD_2$  bypass valve (ETC4UWE) – ECD

GC oven temperatures: FID 60°C;  $ECD_1$  50°C; RGA (pre col) 72 °C,  
RGA (main col) 105 °C;  $ECD_2$  80°C

Detector temperatures: FID 200°C;  $ECD_1$  385°C; RGA 270 °C;  $ECD_2$  385°C

Carrier and detector gases:

FID carrier gas: Helium 5.0 (Messer Griesheim purified with VICI Helium purifier HP2), 30 ml/min; FID detector gases:  $H_2$  ( $H_2$  generator Whatman 75-83) 33 ml/min; air (Messer Griesheim FID-Mix = 60 %  $N_2$ , 40 %  $O_2$ ) 220 ml/min; makeup (He 5.0) 15 ml/min  
 $ECD_1$ : Argon (95%) - Methane (5%) 30 ml/min (Messer Griesheim „ECD-Gas“, purified with Supelco high capacity gas purifier)

RGA: synthetic air 30 ml/min (Messer Griesheim, purified with Molecular Products: Sofnocat 423)

$ECD_2$ : Argon (95%) - Methane (5%) 100 ml/min (Messer Griesheim „ECD-Gas“, purified with Supelco high capacity gas purifier)

For a more detailed description see: Jordan, A. and W. A. Brand (2002)

IsotopeRatioMassSpectrometer [IRMS]: flasks with sampled air – ½” Cajon Ultratorr adaptor – 1/8” stainless steel line - 32 Port Valco multiport valve; 16 probe lines (two for working standard, one for reference gas, 13 for sampled air) each second port blind for evacuating lines before admitting next sample →

*BGC-Air-Trap*: massflow controller (MKS; 60 ml/min, 330 mbar) – Trap1 [water vapour; 1/4” & 1/8” double wall stainless steel, -70°C dry ice/ethanol – valve1 for evacuating] – valve2 (for isolating Trap2) → Trap2 [CO<sub>2</sub> and N<sub>2</sub>O; 1/4” & 1/8” double wall stainless steel / gold, -196°C liquid nitrogen], out freezing and accumulation of CO<sub>2</sub> (needs through passing of ~500 ml sampled air, than closing valve 2 and sucking out the non-condensed air from Trap2; 1/4” line connected to Dual Inlet System of the IRMS) – closing valve3 to isolate trap2. Thaw (~ 20min) and release to the Dual Inlet System / changeover valve via a 100 cm long 0.1 mm i.d. capillary, crimped at the end (Upchurch Scientific; USA) → *Finnigan MAT 252 IRMS* [ionization – acceleration and magnetic deflection – capture in Farraday cups – detection]

For a more detailed description see: Werner, R.A., Rothe, M. and Brand, W.A. (2001) and Werner, R.A., and Brand, W.A. (2001)

**EXPERIMENTAL SET UP**Set up of the modified flight sampling system Ia

½" Decabon<sup>®</sup> tube (length 650 cm) to pump (KNF N 145.1.2.AVE) – ¼" steel tube outlet – 3-way-valve (Swagelok; 1 – pump out, 2 – sample unit, 3 – cockpit) – ¼" Decabon<sup>®</sup> tube (all lines within the sample unit) - coalescing filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GE-15K-FC-03]) – massflow controller (Bronkhorst F201C-FACβ22-V [flushing rate ~10.5 l min<sup>-1</sup>, sampling rate 3.0 l min<sup>-1</sup> at 2 bar abs.]) – vertical drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 71 g] as binder medium (Fluka Chemika 63102) – partikel filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GS-15K-FC-03]) – unidirectional restrictor valve (Swagelok) - mechanical flow controller (only for control purpose, Krohne 0/232939.2) – 3-way-valve (Swagelok; 1 – in, 2 – out →sample unit, 3 – out →restriction outlet 1 bar rel. [Swagelok RL4 (0.7-15bar)]) – analog manometer (Empeo, NR63.14 0-2.5 bar) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½" Cajon Ultratorr shafts (Swagelok) – pressure controller (Bronkhorst P702C-FAC-22-V; restriction 2 bar abs.)

Set up of the modified flight sampling system Ib

½" Decabon<sup>®</sup> tube (length 650 cm) to pump (KNF N 145.1.2.AVE) – ¼" steel tube outlet – 3-way-valve (Swagelok; 1 – pump out, 2 – sample unit, 3 – cockpit) – ¼" Decabon<sup>®</sup> tube (all lines within the sample unit) - coalescing filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GE-15K-FC-03]) – massflow controller (Bronkhorst F201C-FACβ22-V [flushing rate ~10.5 l min<sup>-1</sup>, sampling rate 3.0 l min<sup>-1</sup> at 2 bar abs.]) – partikel filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GS-15K-FC-03]) – unidirectional restrictor valve (Swagelok) - mechanical flow controller (only for control purpose, Krohne 0/232939.2) – 3-way-valve (Swagelok; 1 – in, 2 – out →sample unit, 3 – out →restriction outlet 1 bar rel. [Swagelok RL4 (0.7-15bar)]) – analog manometer (Empeo, NR63.14 0-2.5 bar) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½" Cajon Ultratorr shafts (Swagelok) – pressure controller (Bronkhorst P702C-FAC-22-V; restriction 2 bar abs.)

#### Set up of the ground sampling unit

½“ Decabon<sup>®</sup> tube (length 650 cm) to pump unit (two pumps in row: KNF N 828 KNDC & KNF N 814 KNDC) – ¼“ Decabon<sup>®</sup> tube (all lines within the sample unit) – horizontal drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 66 g] as binder medium (Fluka Chemika 63102) – partikel filter (Gelman, 0.3 micron) – mechanical flow controller (Krohne 0/232939.2) – unidirectional restrictor valve (Swagelok) – analog manometer (Empeo, NR63.14 0-2.5 bar) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½” Cajon Ultratorr shafts (Swagelok) – restriction outlet 1 bar rel. (Swagelok RL4 (0.7-15bar))

#### Set up of the basic flight sampling system

¼“ Decabon<sup>®</sup> tube (length 650 cm) to horizontal drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 69 g] as binder medium (Fluka Chemika 63102) – ¼“ Teflon<sup>®</sup> tube (all lines within the sample unit) – partikel filter (Gelman, 1.0 micron) – pump (KNF N 814 KNDC) – unidirectional restrictor valve (Swagelok) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½” Cajon Ultratorr shafts (Swagelok) – 3-way-valve (Swagelok; 1 – in, 2 – out →flushing, 3 – out →sampling); *for flushing*: – mechanical flow controller (Krohne 0/232939.2) – outlet *for sampling*: – analog manometer (Empeo, NR63.14 0-2.5 bar) – restriction outlet 2 bar abs (TAVCO, 2391244-8-3)

#### Set up of the reference unit

¼“ Decabon<sup>®</sup> tube (length 650 cm) – partikel filter (Gelman, 1.0 micron) – pump (KNF N 814 KNDC) – mechanical flow controller (Krohne 0/232939.2) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon<sup>®</sup> PFA O-rings, prefilled with calibration gas of known trace gas mixing ratios [2 bar abs.] - in and out fixed by ½” Cajon Ultratorr shafts (Swagelok) – restriction outlet 2 bar abs (TAVCO, 2391244-8-3) – mechanical flow controller (Krohne 0/232939.2)

### **EXPERIMENT EXECUTION**

Location: large storage room (Department 'Freiland')

Concurrently operation of all four systems; air was sucked in from one point at the top of the stillage rack.

One complete run was executed with all systems. A solely experiment was afterwards performed operating the modified flight sampling system with altered time intervals for flushing and sampling. Finally one loop was realized with the modified flight sampling system in configuration Ib (without drying compartment), the basic flight sampling system and the reference unit.

Modified flight sampling system:

2 minutes flushing with 10 l min.<sup>-1</sup>, 2 minutes flushing with 3 l min.<sup>-1</sup>, 2 minutes sampling with 3 l min.<sup>-1</sup>

*With altered time intervals*

4 minutes flushing with 3 l min.<sup>-1</sup>, 2 minutes sampling with 3 l min.<sup>-1</sup>

Ground sampling unit:

10 minutes flushing and sampling procedure with 5 l min.<sup>-1</sup>

Basic flight sampling system:

6 minutes flushing, then sampling until the air pressure within the flasks exceeded 2 bar.; flow rate 2 l min.<sup>-1</sup>

Reference unit:

6 minutes flushing and sampling procedure with 1.5 l min.<sup>-1</sup>

**A6 Scale Basis for Triplet Calculations**

*for figures 5.4., 5.8. and 5.11.*

## 10. ACKNOWLEDGEMENTS

At the ending of a study which emerged over a time period of more than three years thank owes to numerous people who contributed either way to the work.

First, I like to thank Prof. Dr. Martin Heimann. His suggestions and the valuable discussions, especially with respect to atmospheric processes and structural aspects, were inspiring and motivation for the work.

Likewise I am very thankful to Prof. Dr. Hartmut Graßl for his incitation, his cooperation and the unhesitant adaptation of an external PhD-student.

I have to thank Prof. Dr. Jon Lloyd, who had to assume the RECAB project and the supervision in the middle of the project. During this time I got a lot of responsibility, discretionary and the chance even for comprehensive studies and experiments.

Prof. Dr. Ernst-Detlef Schulze had taken over the supervision at interim. I am obliged for discussions about processes and interactions with respect to contributions from ecosystems.

For instructive discussions and for the stable isotope analyses of the flask samples I am grateful to Roland Werner, Michael Rothe and Willi Brand. Additional thanks I owe to Armin Jordan for the trace gas analyses and for his patient collaboration.

Christian Rödenbeck and Manuel Gloor sacrificed a lot of their time to introduce me into the basics of modelling. Christian also provided the adjoint transport model calculations. Thanks for the friendly cooperation.

A great experience was the SPA<sup>13</sup>CE experiment. Thanks to all participants and for the opportunity to be part in this inspiring and enjoyable project.

The Freiland group made the tower data from the Hainich available and assisted several times with additional instruments for the field campaigns.

I deserve thank to my colleagues from the RECAB project. On behalf of all participants I acknowledge the project coordinator Ronald Hutjes, and I am grateful to Gorka Pérez-Landa for fruitful discussions about modelling and the provision of the dispersion modelling results and to Beniamino Gioli for the comparison data obtained by the Sky Arrow.

A particular mentioning applies to all colleagues, friends and pilots from Sweden, The Netherlands, Germany, Spain and Italy which tried to achieve the impractical and made the time in the field as pleasant as possible.

Thanks also to Roland von Glasow, who corrected the first draft and gave instructive comments in particular with respect to atmospheric chemistry.

Finally I owe special thanks to Waldemar Ziegler. During all campaigns he was the highly motivated and unfailing fellow who carried every burden without complaining and had to bear my companionship over several weeks under simplest field conditions. I pay my tribute.

The investigations of this study were performed at the Max-Planck Institut für Biogeochemie, Jena, as part of the RECAB project (EVK2-CT-1999-00034), funded by the EU Commission under the 5<sup>th</sup> Framework Programme.

# Summer Field Campaign

27 May – 27 June 2002

# Summer Field Campaign

27 May – 27 June 2002

Flight profile samplings on 15 June above the Roccarespampani location and on 18 June at the mountain site near Orvinio

Sampling heights: 55, 105, 260, 760 and 2745 m above ground.

Sampling times: Morning flights taken place around 3:40 UTC, midday flights were executed around 13:30 UTC.

Aircraft: Morane Socata 894A, 180 HP. Single engine, propeller clockwise. Four seat low wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate  $1 \text{ m s}^{-1}$ . Tube inlet mounted at left wing tip, approximately 15 cm beneath the profile bottom, facing downwards to the front

Ground reference samplings: 13 June 'day time' [15:30 UTC] and 14 June 'night time' [4:30 UTC] at the Roccarespampani site

20 June 'day time' [15:30 UTC] and 21 June 'night time' [5:30 UTC] above meadows close to the Abbey ruin near Orvinio

21 June 'day time' [15:30 UTC] and 22 June 'night time' [4:30 UTC] at the Orvinio mountain site located near the rim

## **Lazio Summer Experiment**

**27 May – 27 June 2002**

To the west the study area is bordered by the Tyrrhenian Sea, the east margin is formed by ridges of the Apennine Mountains. Topography is mostly gentle rolling, but increasing in west-east direction up to 1200 m above MSL.

A stable high pressure cell dominated the weather conditions during the campaign. Caused by clear sky very high air temperatures were observed on all days, which were 5°C above the long year average for this period. Temperature maxima at the ground around noon of about 37°C were reached on most days. During morning hours wind was nearly calm, also in the afternoon wind speed did not exceed 3.5 m sec.<sup>-1</sup>, mainly from southern and western directions. No precipitation was recorded through the time.

Vertical profile flights were performed at two different sites: above the deciduous forest of Roccarespampani, labelled 'Tuscania' (160 m above MSL) and above a mountain site called 'Orvinio', with grasslands and meadows surrounded by forests (850 m above MSL). Two flights were planned per day, with sampling at five levels. The uppermost level had to be defined at this great altitude, since an extended increasing of the CBL during day time was expected because of the strong thermal convection.

Additional air samples were collected during night and day time. Near surface measurements were carried out in the Roccarespampani forest, above the meadows of the mountain valley and close to the forested ridge.

# Summer Field Campaign

27 May – 27 June 2002

- Title            MODIS image of Italy from 25 March 2003 (NASA).
- Figure 1        Aerial photograph of Roccarespampani Forest and its surrounding from 2750 m above ground.
- Figure 2        Location of Roccarespampani reference site from low flight level.
- Figure 3        ‘Orvinio’ mountain site. Central part of the bowl shaped valley from 300 m above ground.
- Figure 4        Photograph taken from the lowest sampling level during the morning flight at the ‘Orvinio’ location.

([http://maps.geog.umd.edu/GlobalFires\\_HTML](http://maps.geog.umd.edu/GlobalFires_HTML))

**Figure 9** Fires detected by the MODIS sensor between 4 and 18 June 2002 in Northern America ([http://maps.geog.umd.edu/GlobalFires\\_HTML](http://maps.geog.umd.edu/GlobalFires_HTML))

Back trajectories of air particles calculated from a receiving point at the 2750 m sampling level above the 'Orvinio' location on 17 June 2002 21:30 UTC (red) and on 18 June 2002 11:30 UTC (green)

## Description of table parameters

**date&time (GMT)** - date and time the sampling procedure was completed in Greenwich Mean Time

**flask code** - marking of nameplates for each flask

**site** - location of the flight pattern, leg length ~2km

Orvi - flight track, mountain site north of the little village of Orvinio; agricultural area, valley (bowl like)

Tusca - flight track east of Tuscania (Roccarespampani Fluxnet site), oak forest, agricultural area

ground sampling location

Rocca - Roccarespampani Fluxnet site, oak forest: 42°24.0'N / 011°55.0'E, 178 m a. MSL

Orv-Abt - mountain site, valley bottom nearby ruin of Romanic abbey Santa Maria del Piano, meadow: 42°08'N / 12°57'E, 682 m a. MSL

Orv-Val - mountain site, slope near the ridge, oak forest: 42°08'N / 12°53'E, 959 m a. MSL

**alt (ft)** - sampling height in feet above ground

**init p.** - internal flask pressure at the beginning of the analysis

## Mixing ratios

	Precision of the analyses
<b>CH<sub>4</sub> [ppb]</b> - methan mixing ratio in ppb	1.3 ppb
<b>CO<sub>2</sub> [ppm]</b> - carbon dioxide mixing ratio in ppm	0.08 ppm
<b>N<sub>2</sub>O [ppb]</b> - nitrous oxide mixing ratio in ppb	0.15 ppb
<b>CO [ppb]</b> - carbon monoxide mixing ratio in ppb	1.0 ppb
<b>H<sub>2</sub> [ppb]</b> - hydrogen mixing ratio in ppb	5.0 ppb
<b>SF<sub>6</sub> [ppt]</b> - sulfur hexafluoride mixing ratio in ppt	0.08 ppt

## Isotope Ratio

$d[\$] = (R_{sa}/R_{ref} - 1) \cdot 1000$       $R_{sa}$  and  $R_{ref}$  are the sample and reference isotope ratios

**del <sup>13</sup>C [\\$]** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del <sup>18</sup>O [\\$]** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

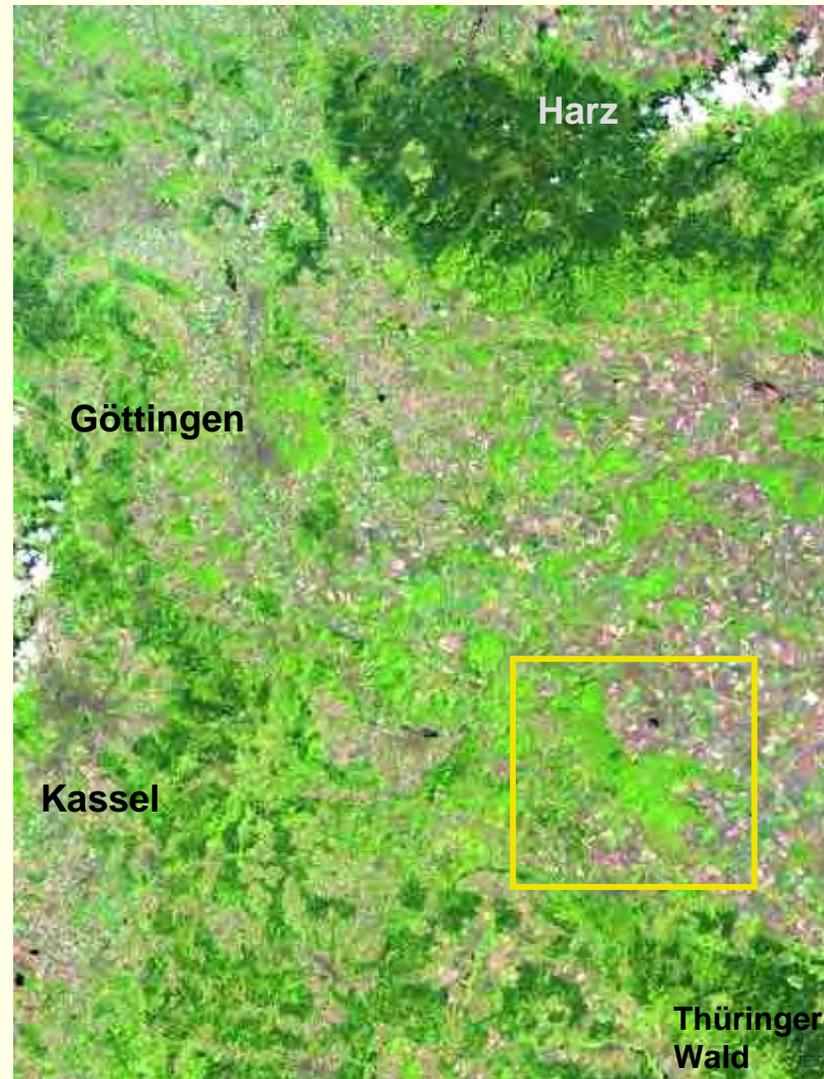

Precision of the analyses    <sup>13</sup>C = 0.012 \$    <sup>18</sup>O = 0.02 \$

date&time [GMT]	flask code	site	alt [ft]	init p.	mixing ratios						isotope	
					CH <sub>4</sub> [ppb]	CO <sub>2</sub> [ppm]	CO [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	N <sub>2</sub> O [ppb]	del <sup>13</sup> C [‰]	del <sup>18</sup> O [‰]

# SPA<sup>13</sup>C – Soil Plant Atmosphere <sup>13</sup>C Exchange Experiment

29 July – 16 August 2002

# SPA<sup>13</sup>CE – Soil Plant Atmosphere <sup>13</sup>C Exchange Experiment

29 July – 16 August 2002

## Participants

N. Buchmann, V. Hahn, A. Knohl, M. Schumacher, U. Seibt, A. Sørensen (MPI-BGC Jena) and L. Wingate\*

Flight profile samplings on 6, 14 and 15 August above the Hainich

(additional on 9 August at Aerocarb [Airborne European Regional Observation of the Carbon Balance] measurement site 'Holzland')

Sampling heights: The lowest flight level was following the canopy at a height of almost 8 - 10 m above the treetop. Heights of the other sampling levels were 140, 275, 825 and 1370 m above ground.

Sampling times: Morning flight on 14 August around 8:00 UTC, on 15 August around 7:00 UTC. Midday flights were executed around 10:30 UTC on both days; the flights on 6 August were performed around 7:20 and 12:30 UTC.

Aircraft: Wilga-35, 260 HP. Single 9-cylinder radial engine, propeller clockwise. Four seat shoulder wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate 1 m s<sup>-1</sup>. Tube inlet mounted at left wing tip, approximately 15 cm beneath the profile bottom, facing downwards to the front

\* University of Edinburgh

## **SPA13CE Thuringia Summer Experiment**

**Flights 6 – 15 August 2002**

### **Combined ground level and flight investigations**

During the first two weeks of August intensive measurement activity of PhD. students from the MPI-BGC had taken place at the Hainich National Park.

Because of foggy conditions in the morning the flights started not at the same time on all days; on 14 August around 8:00 UTC, on 15 August around 7:00 UTC. Midday flights were carried out around 10:30 UTC on both days. The lowest flight level was following the canopy surface at a height of almost 8 - 10 m (see also thesis figure 2.4). Special focus of the study was on the two consecutive days at the end of the experiment.

The synoptic situation of this period was characterized by a low pressure cell that had passed the study area the days before. On the 14 August this cyclone was located over Poland and the Baltic States, moving further on to the south-east. From the Tyrrhenian Sea to Scandinavia a high pressure bridge established, while in the West low pressure cells were moving from the Mid-Atlantic, passing the Orkneys, to the north-east. On both days no precipitation was observed, but in the early morning fog occurred at the valley grounds.

# SPA<sup>13</sup>C – Soil Plant Atmosphere <sup>13</sup>C Exchange Experiment

29 July – 16 August 2002

- Figure 1 Southern Hainich with marked tower location. View to the East inside the Thuringian Basin.
- Figure 2 Hainich Tower and canopy with shadow of the aircraft..
- Figure 3 Hainich Tower from the ground.
- Figure 4 View from the highest boom mounted on the Hainich Tower above the canopy to the West.
- Figure 5 Small mast beside the main tower used for near ground measurements.
- Figure 6 Branch bag with beech twig for plant related measurements and air sampling.
- Figure 7 Air sampling from branch bags with a similar system as used for the flight samplings during the begin of the RECAB project.
- Figure 8 Soil respiration air sampling.
- Figure 9 Picture of the Hainich Tower taken when passing while sampling at lowest flight level.

**Figure 1** Aerial photograph of the southern Hainich with the tower location (marked by the yellow arrow), viewing to the East inside the Thuringian Basin. Flight altitude approximately 1500 m above ground.

Picture: 16 February 2001

**Figure 2** Hainich Tower (height 42 m, treetops around 35 m). Flight altitude approximately ~ 25 m above the canopy. Picture taken at noon on 15 August 2002.

**Figure 3** Hainich Tower from the ground. Notice the booms with the measurement equipments and the inlets for air sampling. Surrounding canopy is from ash trees.

Picture: 6 August 2002

**Figure 4** View from the Hainich Tower over the canopy to the South. Placed on the boom are the sensors for radiation measurements.

Picture: 6 August 2002

**Figure 5** Small mast for near ground measurements close to the main tower (height 3.0 m).

Picture by A. Knohl

**Figure 6** Branch bags with enclosed beech twig for direct sampling of air characterized by assimilation and respiration.

Picture: 6 August 2002

**Figure 7** Air sampling from branch bags. The configuration of the flask sampling system is similar to the design of the system used at the beginning of the flight investigations.

Picture by A. Knohl

**Figure 8** Soil respiration sampling from cylindric sections as visible in the front (right hand site of the sketch book). Filling of small cuvettes for isotopic analyses. Inside the big ,chimney' flask sampling profiles of respired air were carried out.

Picture: 6 August 2002

**Figure 9** Hainich Tower (height 42 m, treetops around 35 m). 'Lowest level' sampling altitude approximately 5 - 7 m above the canopy.

Picture at noon on 15 August 2002

## PARAMETER/VARIABLE DESCRIPTION

**date&time (GMT)** - date and time the sampling procedure was completed in Greenwich Mean Time

**flask code** - marking of nameplates for each flask

**site** - location of the flight pattern, leg length ~2km

Ground sampling / reference location: *Hainich Tower*

Hainich Fluxnet site, deciduous forest: 51°04.7N / 010°27.1'E, 439 m a. MSL

**alt (ft)** - sampling height in feet above ground

**init p.** - internal flask pressure at the beginning of the analysis

### Mixing ratios

	Precision of the analyses
<b>CH<sub>4</sub> [ppb]</b> - methan mixing ratio in ppb	1.3 ppb
<b>CO<sub>2</sub> [ppm]</b> - carbon dioxide mixing ratio in ppm	0.08 ppm
<b>N<sub>2</sub>O [ppb]</b> - nitrous oxide mixing ratio in ppb	0.15 ppb
<b>CO [ppb]</b> - carbon monoxide mixing ratio in ppb	1.0 ppb
<b>H<sub>2</sub> [ppb]</b> - hydrogen mixing ratio in ppb	5.0 ppb
<b>SF<sub>6</sub> [ppt]</b> - sulfur hexafluoride mixing ratio in ppt	0.08 ppt

### Isotope Ratio

$d[\$] = (R_{sa}/R_{ref} - 1) \cdot 1000$        $R_{sa}$  and  $R_{ref}$  are the sample and reference isotope ratios

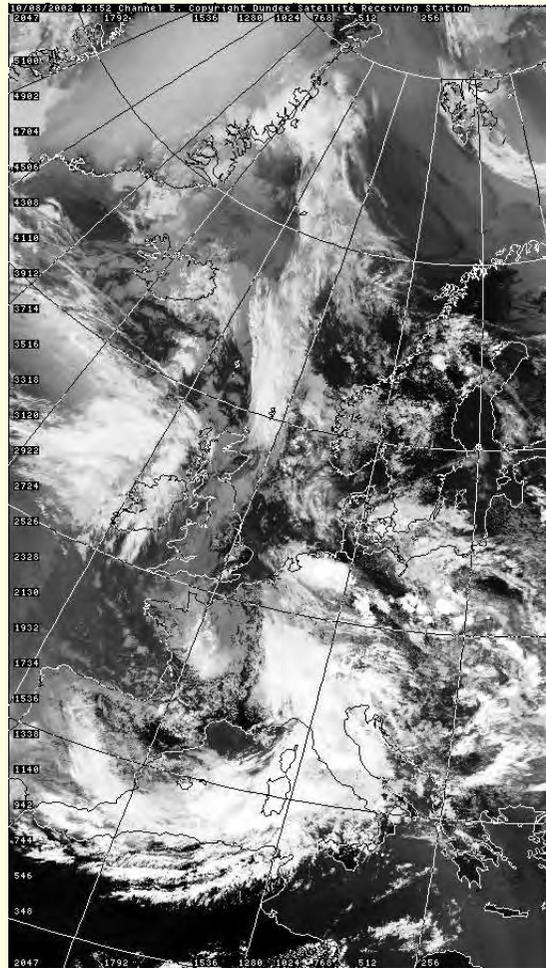

**del <sup>13</sup>C [\\$]** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del <sup>18</sup>O [\\$]** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

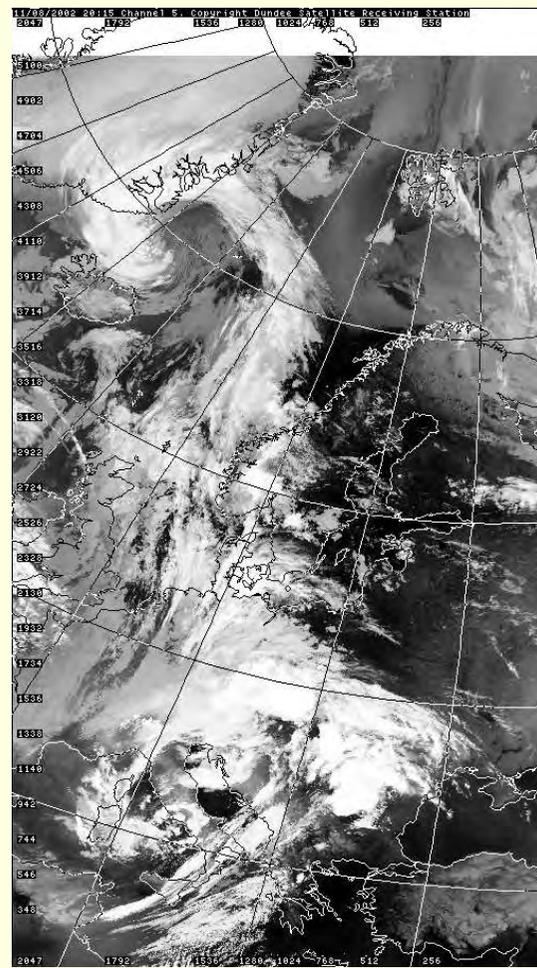

Precision of the analyses    <sup>13</sup>C = 0.012 \$      <sup>18</sup>O = 0.02 \$

location	alt [m]	collection time (GMT)	mixing ratio			mixing ratio			isotopes [‰]		Flask No.

- Figure 10       Ground reference site ‘Maizefield’ – pictures from the winter and the summer campaign.
- Figure 11       Aerial photograph of the marshland near the ground reference site.
- Figure 12       MODIS satellite images from 15 and 27 July 2002.

# Winter Field Campaign

14 January – 10 February 2002

Flight profile samplings: 25, 29 and 31 January above the 'Forest' and the 'Maize' location,  
30 January above the 'Forest' and the 'Cabauw' site.

2 February above all three locations 'Forest', 'Maize' and 'Cabauw'

Sampling heights: 60, (100), 150, (300) and 900 m above ground.

Sampling times: Morning flights around 10:00 UTC, midday flights around 14:00 UTC.

Aircraft: Piper PA28, 180 HP. Single engine, propeller clockwise. Four seat low wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate  $1 \text{ m s}^{-1}$ . Tube inlet mounted at left wing tip, approximately 15 cm beneath the profile bottom, facing downwards to the front.

Ground reference samplings: 'Loobos' on 4 February 'night time' [6:30 UTC], on  
5 February 'day time' [13:00 UTC] and again 'night time' on  
6 February [6:30 UTC]

'Maisfeld' on 4 February 'morning' [9:00 UTC] and 'day time'  
[13:00 UTC] and on 5 February 'night time' [6:30 UTC]

'Cabauw' on 6 February 'day time' [13:00 UTC] and on  
7 February 'night time' at [6:30 UTC]

# The Netherlands Winter Experiment

14 January – 10 February 2002

## Test of the improved sampling strategy

A mosaic, formed by four major land form units, is characterizing the study region located within the central Netherlands: Two glacial ridges, orientated from south to north, are bearing mixed coniferous and deciduous forests or heathers. Most prominent is a mixture of agricultural land, commonly maize and grasslands, which is scattered by rural settlements. The marshlands, which are more frequent at the western edge of the study region and along the rivers, are predominately used for animal farming. At the margins and within the study region some large urban agglomerations are located; Rotterdam, Amsterdam and Utrecht, and the smaller cities Amersfoort, Ede and Apeldoorn.

Climatic conditions are specified by mean annual values for temperature of 9.5°C and precipitation of 750 – 950 mm. Compared with the German sites a more maritime character is obvious. Mean wind speed is around 4 m sec.<sup>-1</sup>, most frequent are south-westerlies. During the campaign took place the weather conditions were quite unstable and in particular with respect to the air temperature not representative. The last decade of January was the warmest period recorded since 1901, the measured 15.5°C at the 2 February was even the highest temperature ever observed at this day of the year. Heavy south-westerly storms passed the region during the night times of the 26 and the 28 January.

Profile flights were performed at three different sites: above a mixed broadleaf and coniferous forest on all days, combined with sampling above a mixed agricultural, scattered populated area on three days and with sampling above marshland north of the tall Cabauw Tower on two days.

From the results of the last laboratory experiment, which was performed to analyse probable impairments caused by the drying agent (see chapter 3.2.2.), the time and operational scheme for flushing and sampling were adjusted to a new flushing duration of each 2 minutes with 10.5 l min<sup>-1</sup> respectively 3.0 l min<sup>-1</sup> and to a final 2 minute sampling period with a flow rate of 3.0 l min<sup>-1</sup>.

**Figure 1** Satellite image of the study region. The locations where the vertical profile flights were performed are marked by the red stars.

**Figure 2** Study area 'Maize' dominated by agriculture use. Viewing north-west.

Picture: afternoon 2 February 2002

**Figure 3** 'Cabauw' location, viewing west. Marked are the tall 'Cabauw Tower' and the ground reference site where flask samplings were carried out.

Picture: 2 February 2002

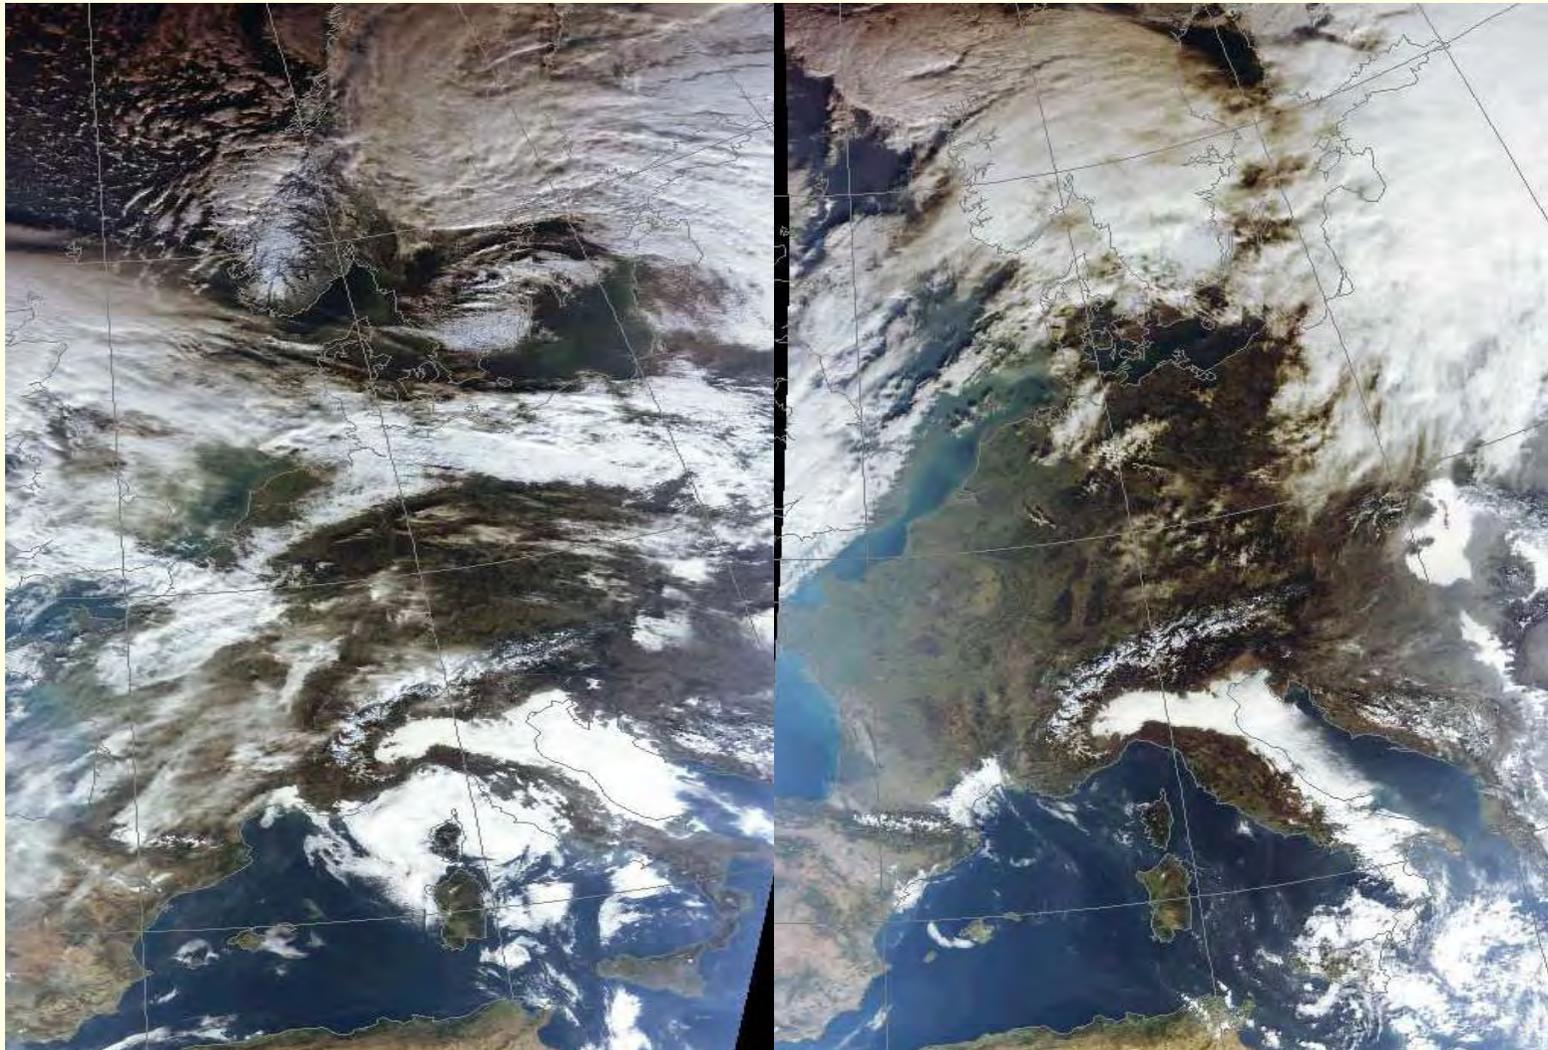

**Figure 4** Combined measurements with the 'SkyArrow' above the 'Forest site' at highest sampling level  
~ 900 m above ground.

Picture: 29 January 2002

**Figure 5** Ground reference sites: 'Forest' nearby the Loobos Fluxnet tower (left), the 'Maizefield' location (upper right panel) and the 'Marshland' site north of the Cabauw Tower.

29 January 2002 10:40 UTC

2 February 2002 10:15 UTC

RGB composite image reprojected (RGB 1,4,3 composite)

# Summer Field Campaign

10 – 28 July 2002

Enhancement of the improved sampling strategy

Flight profile samplings: 15, 16 and 27 July above all profile sites 'Forest', 'Maize' and 'Cabauw'

Sampling heights: 60, 150, 900 and 1700 m above ground.

Sampling times: Morning flights started around 7:30 UTC, midday flights around 12:30 UTC.

Aircraft: Piper PA28, 180 HP. Single engine, propeller clockwise. Four seat low wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate  $1 \text{ m s}^{-1}$ . Tube inlet mounted at left wing tip, approximately 15 cm beneath the profile bottom, facing downwards to the front.

Ground reference samplings: within the maizeland on 18 July 'night time' [4:00 UTC],  
'midday' [11:00 UTC] and 'afternoon' [15:30 UTC]  
above the marshland on 28 July 'night time' [4:00 UTC],  
'midday' [12:30 UTC] and 'afternoon' [16:30 UTC]

As during the winter experiment the weather was unstable. Relatively colder and wetter conditions than expected from the long year averages were dominant.

Profiles were carried out at the identical locations as before, but combining this time all sites.

Additional ground reference studies were executed at the identical plots within the maize field and close to the Cabauw tower.

**Figure 7** Marshland north of the Cabauw Tower. In the centre the tall 'Cabauw Tower'. Flight altitude approximately 150 m above ground.

**Figure 8** Surrounding of the ground reference site 'Maizefield' (marked by the yellow arrow). Picture taken on 27 July from approximately 300 m above ground.

**Figure 9** Above the forest study area. The MFP 'SkyArrow' passes the site on its transect while vertical profile is performed for flask sampling.

Picture: 16 July 2002

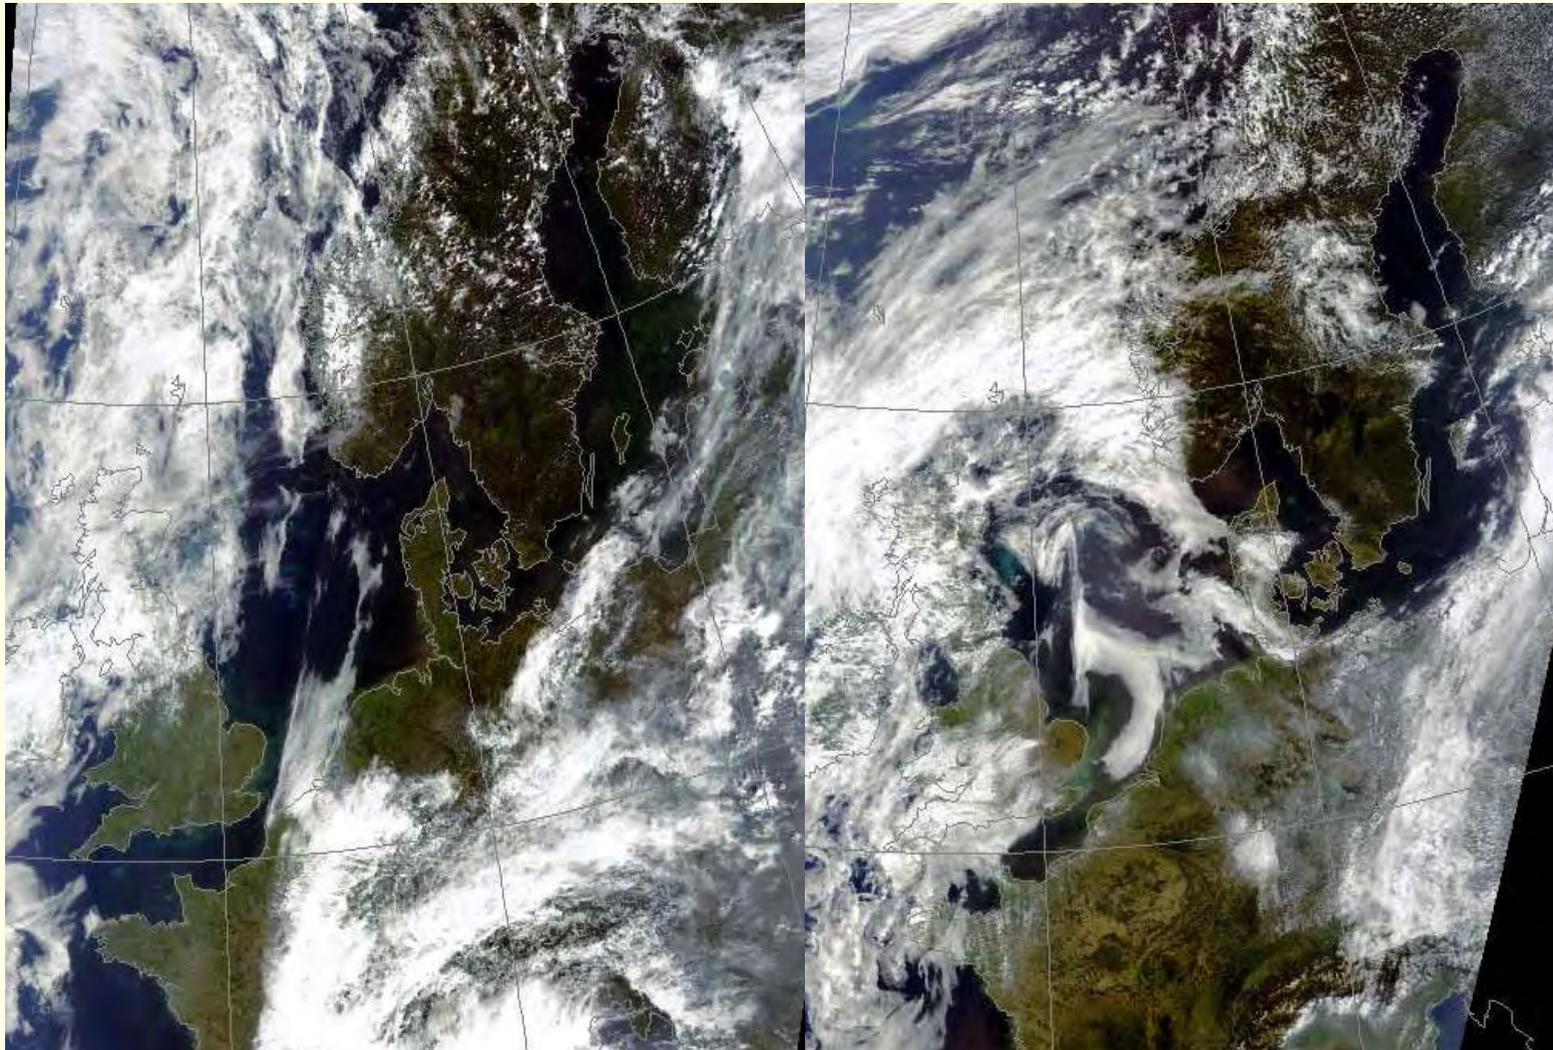

**Figure 10** Ground reference site 'Maizefield' – upper panel on 4 February 2002, below on 18 July 2002

**Figure 11** Aerial photograph of the marshland area. The ground reference unit was located close to the top left corner (yellow arrow). Flight altitude approximately 150 m above ground, viewing east.

Picture: 27 July 2002

15 July 2002 10:45 UTC

27 July 2002 11:10 UTC

**Figure 12** MODIS Satellite Images (from Dundee Satellite Receiving Station) Satellite: Terra Sensor: MODIS  
RGB composite image reprojected (RGB 1,4,3 composite)

## Description of table parameters

**date&time** - date and time the sampling procedure was completed in Greenwich Mean Time

**Flask code** - marking of nameplates for each flask

**site** - location of the flight pattern, leg length ~2km

Mais - flight track, agricultural area, small villages, isolated farms, fertilizer factory  
starting point south-east corner: 52°07'N / 5°40'E

Forst - flight track northwest of Vaassen (Apeldoorn), mixed forest, open heather  
starting point south-east corner: 52°16'N / 5°54'E

Cabauw - flight track northeast of the Cabauw tower; marsh lands, small villages  
turning point north-west corner: 52°00'N / 4°55'E

Loobos - ground reference sampling within a coniferous forest near the fluxnet tower  
site 'Loobos': 52°10'N / 5°44'E

Maisfeld - ground reference sampling at a bare agricultural plot (former maize  
cultivation): 52°09'N / 5°43'E

Cabauw - ground reference sampling north of the tall Cabauw Tower at grassland on  
wet marsh soil: 51°59'N / 4°56'E

**alt** - sampling height in meter above ground, referring to the place of departure

**init p.** - internal flask pressure at the beginning of the analyses

## Mixing Ratios

	Precision of the analyses
<b>CH<sub>4</sub> [ppb]</b> - methane mixing ratio in ppb	1.3 ppb
<b>CO<sub>2</sub> [ppm]</b> - carbon dioxide mixing ratio in ppm	0.08 ppm
<b>N<sub>2</sub>O [ppb]</b> - nitrous oxide mixing ratio in ppb	0.15 ppb
<b>CO [ppb]</b> - carbon monoxide mixing ratio in ppb	1.0 ppb
<b>H<sub>2</sub> [ppb]</b> - hydrogen mixing ratio in ppb	5.0 ppb
<b>SF<sub>6</sub> [ppt]</b> - sulphur hexafluoride mixing ratio in ppt	0.08 ppt

## Isotope Ratios

$$\delta[\text{\$}] = (R_{\text{sa}}/R_{\text{ref}} - 1) \cdot 1000$$

$R_{\text{sa}}$  and  $R_{\text{ref}}$  are the sample and reference isotope ratios

**del <sup>13</sup>C [\\$]** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del <sup>18</sup>O [\\$]** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

Precision of the analyses <sup>13</sup>C = 0.012 \$    <sup>18</sup>O = 0.02 \$

## Description of table parameters

**date&time** - date and time the sampling procedure was completed in Greenwich Mean Time

**Flask code** - marking of nameplates for each flask

**site** - location of the flight pattern, leg length ~2km

Mais - flight track, agricultural area, small villages, isolated farms, fertilizer factory  
starting point south-east corner: 52°07'N / 5°40'E

Forst - flight track northwest of Vaassen (Apeldoorn), mixed forest, open heather  
starting point south-east corner: 52°16'N / 5°54'E

Cabauw - flight track northeast of the Cabauw tower; marsh lands, small villages  
turning point north-west corner: 52°00'N / 4°55'E

Maisfeld - ground reference sampling at a bare agricultural plot (former maize  
cultivation): 52°09'N / 5°43'E

Marsch - ground reference sampling north of the tall Cabauw Tower at grassland on  
wet marsh soil: 51°59'N / 4°56'E

**alt** - sampling height in meter above ground, referring to the place of departure

**init p.** - internal flask pressure at the beginning of the analyses

## Mixing Ratios

	Precision of the analyses
<b>CH<sub>4</sub> [ppb]</b> - methane mixing ratio in ppb	1.3 ppb
<b>CO<sub>2</sub> [ppm]</b> - carbon dioxide mixing ratio in ppm	0.08 ppm
<b>N<sub>2</sub>O [ppb]</b> - nitrous oxide mixing ratio in ppb	0.15 ppb
<b>CO [ppb]</b> - carbon monoxide mixing ratio in ppb	1.0 ppb
<b>H<sub>2</sub> [ppb]</b> - hydrogen mixing ratio in ppb	5.0 ppb
<b>SF<sub>6</sub> [ppt]</b> - sulphur hexafluoride mixing ratio in ppt	0.08 ppt

## Isotope Ratios

$$\delta[\text{\$}] = (R_{\text{sa}}/R_{\text{ref}} - 1) \cdot 1000$$

$R_{\text{sa}}$  and  $R_{\text{ref}}$  are the sample and reference isotope ratios

**del <sup>13</sup>C [\\$]** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del <sup>18</sup>O [\\$]** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

Precision of the analyses <sup>13</sup>C = 0.012 \$      <sup>18</sup>O = 0.02 \$

# Summer Field Campaign Thuringia

15 July – 2 August 2001

# Summer Field Campaign

15 July – 2 August 2001

Flight profile samplings on 17, 21, and 23 July above the Gebesee agricultural site and on 24 and 25 July above the Hainich

Sampling heights: Because of clouds the sampling heights had to be adapted sometimes between the flights. Lowest sampling level at Gebesee site was 100 m, above the Hainich 90 m above ground. Since the development of the CBL varied between the days and due to the power capability of the aircraft (related with air temperature) the top height differs from 1800 to 2500 m above ground.

Sampling times: Morning flights around 8:45 UTC, midday flights around 12:30 UTC, afternoon flights around 16:30 UTC.

On 17 and 25 July only two flights per day, caused by fog in the morning and technical problems with the sampling unit, respectively.

Aircraft: Wilga-35, 260 HP. Single 9-cylinder radial engine, propeller clockwise. Four seat shoulder wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate  $1 \text{ m s}^{-1}$ . Tube inlet mounted at right wing tip, approximately 10 cm beneath the profile bottom, facing downwards to the front

## **Summer Field Campaign**

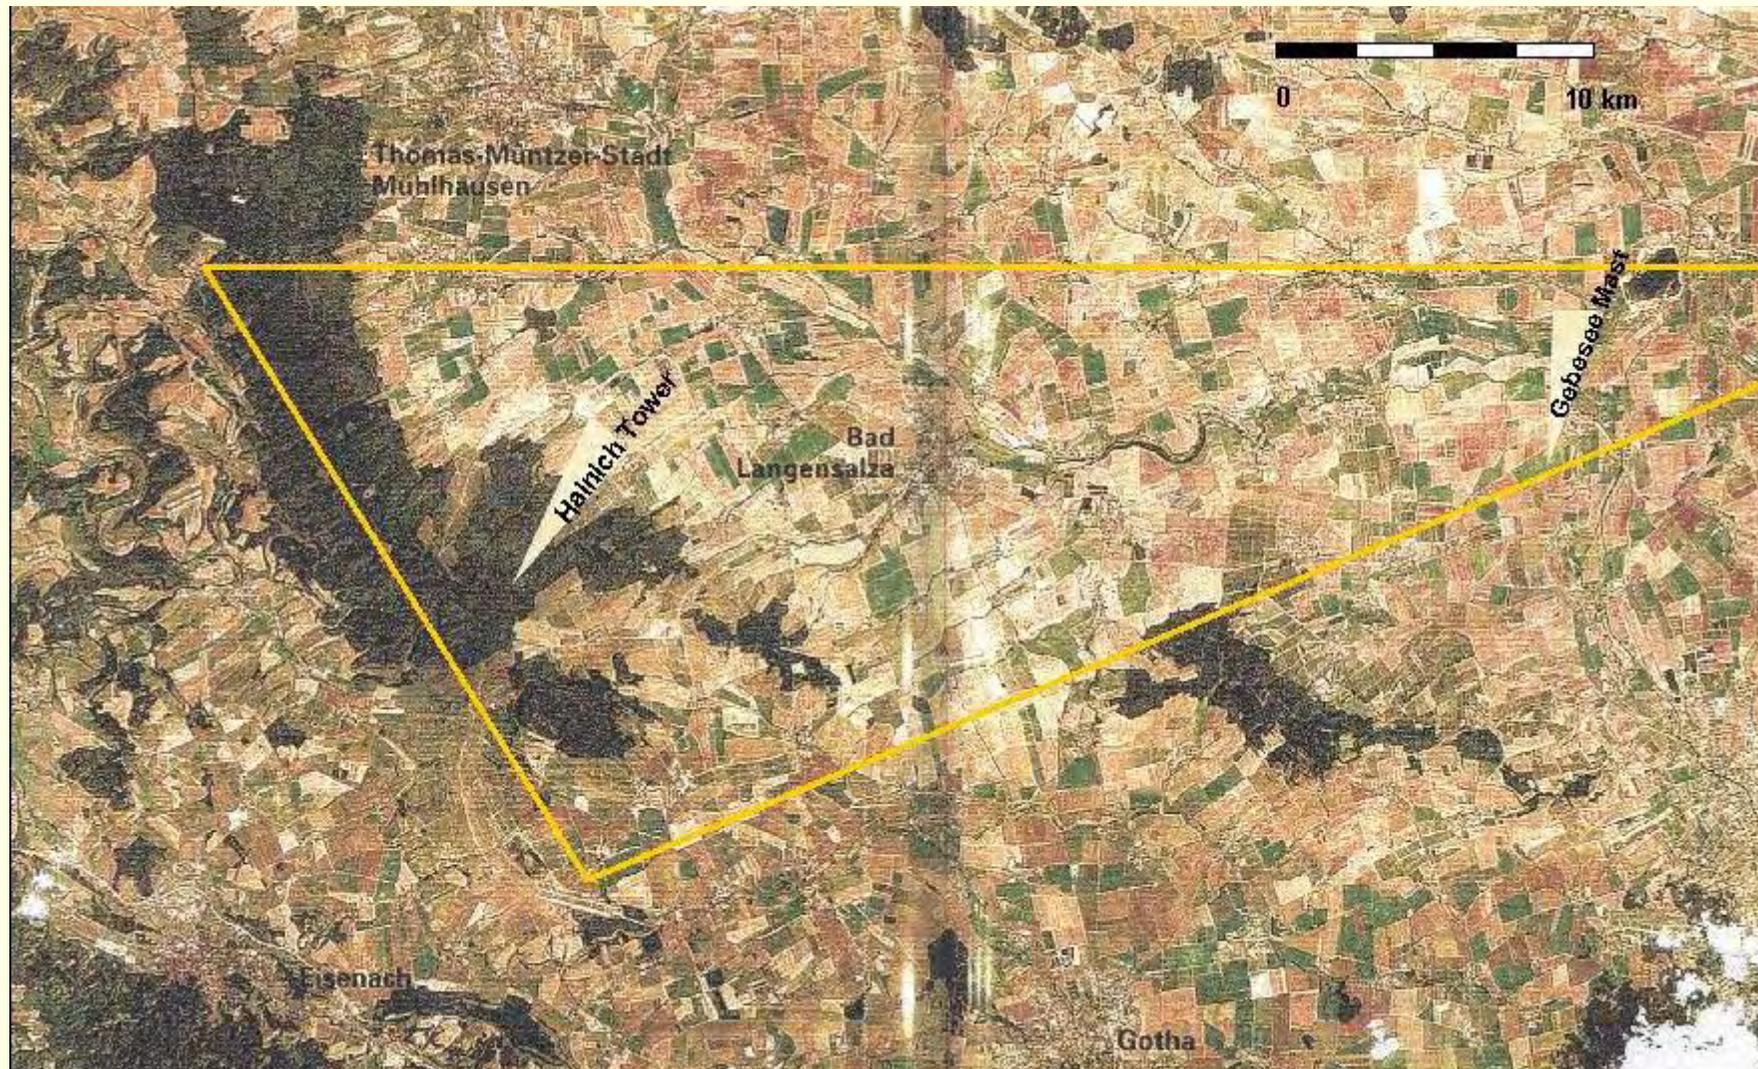

**15 July – 2 August 2001**

During the campaign only small air pressure contrasts occurred over Central Europe. A stable high pressure zone over Russia was dominant, faint low pressure cells crossed the region between 19 and 21 July. From 22 July on high pressure conditions were dominating. A low pressure area, generated on 23 July west of Greenland, did not affect the region until the end of the campaign. In July 2001 the temperature anomaly recorded at Erfurt Airport was +1.5°C, the amount of the precipitation was 161% of the 30-year-average (1961 – 1990). Until 15 July the cumulative sum of rain was 67.7 mm, which was 81 % of the monthly total amount. After 21 July no more precipitation was recorded.

- Figure 3      Hainich Tower from 300 m above ground.
- Figure 4      MODIS Satellite Images of Central Europe; 23 and 24 July 2001

**Figure 1** Satellite image of the study region with the locations of the towers, where vertical profile flights were performed, and flight track of the MobileFluxPlatform 'SkyArrow'.

Image taken from Winter et al. 1998 (modified)

**Figure 2** Gebesee agricultural study site. The flux tower is marked by the yellow circle. Most of the grain fields are still harvested. Flight altitude approximately 1000 m above ground, viewing south-east.

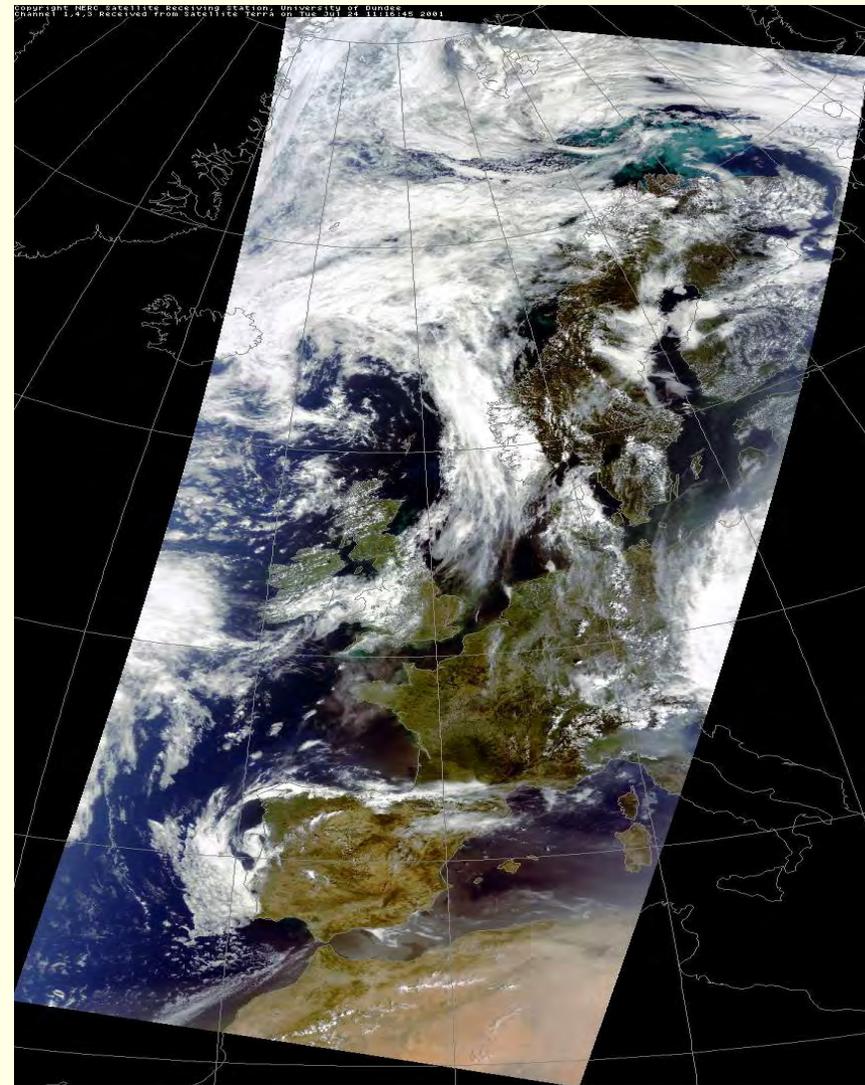

Picture: late afternoon 25 July 2001

**Figure 3** Aerial photograph of the Hainich Tower (located in the center). Flight altitude approximately 300 m above ground. Picture: 25 July 2001

23 July 2001 10:33 UTC

24 July 2001 11:16 UTC

**Figure 4** MODIS Satellite Images (from Dundee Satellite Receiving Station) Satellite: Terra Sensor: MODIS  
RGB composite image reprojected (RGB 1,4,3 composite)

## Description of table parameters

**date&time** - date and time the sampling procedure was completed in Greenwich Mean Time

**Flask code** - marking of nameplates for each flask

**Site** - location of the flight pattern, tower sites

Gebesee, agricultural site north of Erfurt, 6 m tower; 51°06,1'N / 10°55,0'E, 162 m a.MSL

Hainich, beech forest north of Eisenach, 42 m tower; 51°04,7'N / 10°27,1'E, 439 m a.MSL

**alt** - sampling height in meter above ground, referring to the place of departure

### Mixing ratios

### **Precision of the analyses**

**CH4 [ppb]** - methane mixing ratio in ppb

1.3 ppb

**CO2 [ppm]** - carbon dioxide mixing ratio in ppm

0.08 ppm

**N2O [ppb]** - nitrous oxide mixing ratio in ppb

0.15 ppb

### Isotope Ratio

$$\delta[\$] = (R_{sa}/R_{ref} - 1) \cdot 1000$$

$R_{sa}$  and  $R_{ref}$  are the sample and reference isotope ratios

**del 13C** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del 18O** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

Precision of the analyses  $^{13}\text{C} = 0.012 \text{ ‰}$   $^{18}\text{O} = 0.02 \text{ ‰}$

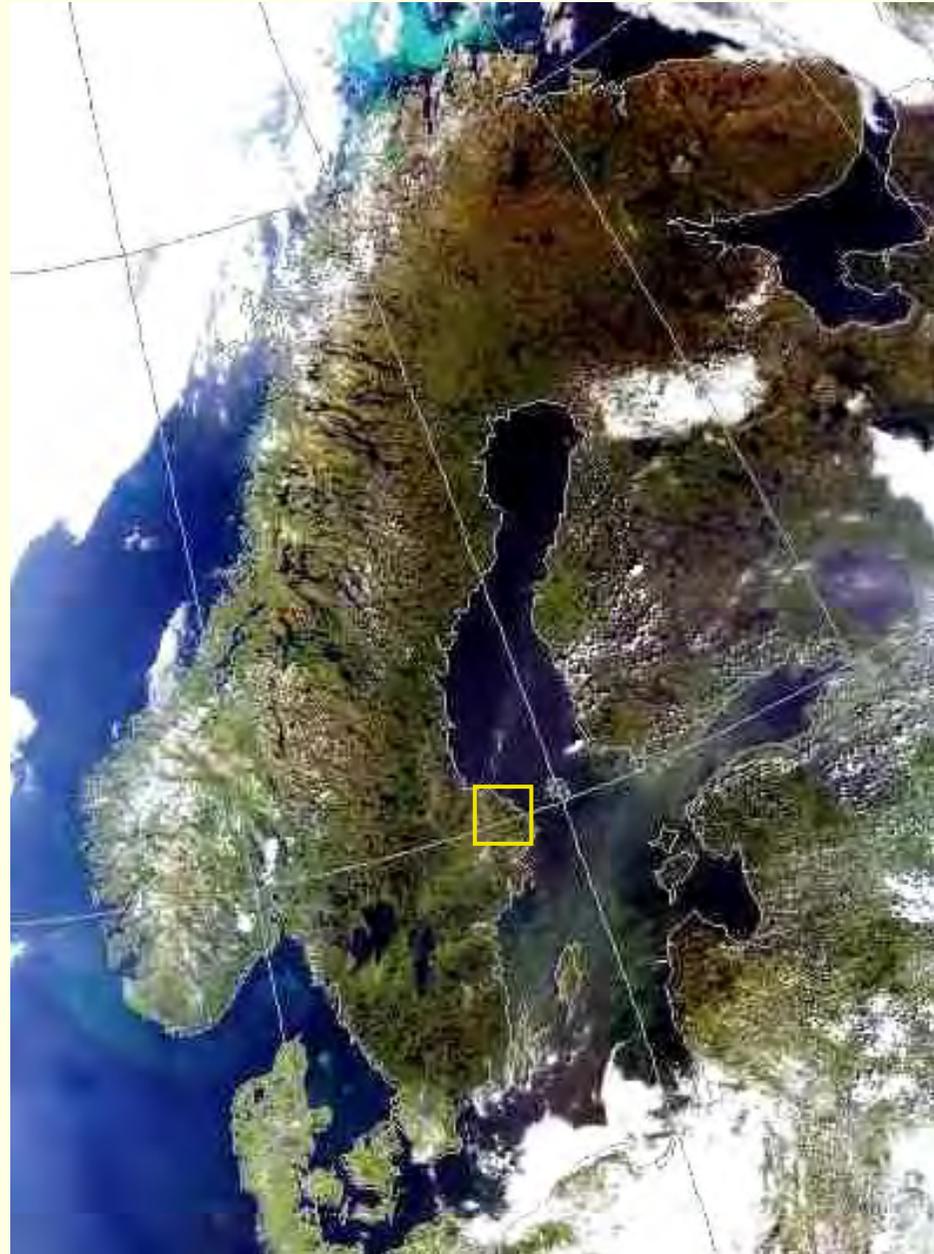

**Because of problems with the sampling system a number of flasks (24<sup>th</sup> and 25<sup>th</sup> July) were not filled with overpressure. These flasks (laid underneath in yellow colour) were analyzed separately in April 2002 and are not directly comparable – be aware of this!!!**

date & time (GMT)	flask code	site	alt [m]	mixing ratio			isotope ratios	
				CH <sub>4</sub> [ppb]	CO <sub>2</sub> [ppm]	N <sub>2</sub> O [ppb]	del <sup>13</sup> C [‰]	del <sup>18</sup> O [‰]

# Summer Field Campaign

10 August – 9 September 2001

# Summer Field Campaign

10 August – 9 September 2001

Flight profile samplings on 16, 17, 18 and 19 August around the Norunda Tower and on 29, 30 August and 1 September above the 'Florarna' wetland site

Sampling heights: 60/90, 150, 290, 760/975 and 1980 m above ground.

Sampling times: Morning flights taken place around 5:40 UTC, midday and afternoon flights were executed around 12:00 UTC, respectively 17:00 UTC.

Aircraft: Piper PA28-180, 180 HP. Single engine, propeller clockwise. Four seat low wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate  $1 \text{ m s}^{-1}$ . Tube inlet mounted at right wing tip, approximately 20 cm beneath the profile bottom, facing downwards to the front

Ground reference samplings: 29 August 'day time' [13:00 UTC] and 30 August 'night time' [2:30 UTC] above the open swamp

1 September 'day time' [13:00 UTC] and 2 September 'night time' [2:30 UTC] inside the wooded area (slight rain)

5 September 'day time' [13:00 UTC] and 6 September 'night time' [2:30 UTC] inside the wooded area

# Uppland Summer Experiment

11 August – 9 September 2001

## Implementation of additional trace gas analyses

Located about 150 km north of Stockholm the 'Uppland' study region was the most northern one within the RECAB project. With its mixture of forests (44 % & 18.5 % clear cuts), agricultural areas (27 %), lakes and wetlands (8 %) the region is representative for the Southern Scandinavian boreal forest zone. The area is topographically and morphologically very uniform; almost flat with an elevation of 30 – 70 m above MSL. In the southern part the soils are dominated by sand and silt, whereas to the north the fraction of till material and bogs increase [Lindroth 2003].

During summer south-westerly winds are prevalent. Because of the location at the margin of the Gulf of Bothnia the area is characterized by relative maritime climatic conditions, compared to the boreal forest further inland. Mean annual temperature is 5.5°C, mean annual precipitation is around 730 mm. On the 16<sup>th</sup> August a heavy rain shower occurred. Slight rainfall was observed on 20 August, and two more rainy days followed on 27 and 28 August. The maximum of the daily temperature exceeded 20°C on most days. First night with temperature below 0°C was on 30 August.

Data collection was carried out by performing an adapted flight and sampling strategy around the Norunda Tower (coniferous forest with some agricultural used areas in between) and above the Florarna nature reserve (natural wetland). Additional ground level measurements and air sampling was carried out for reference data recordings concurrently with the flight investigations at the Florarna site. Therefore the new mobile mast was installed for a few days within the open swamp and for some more days inside a wooded area of the wetland.

# Summer Field Campaign

10 August – 9 September 2001

## Description of table parameters

**date&time** - date and time the sampling procedure was completed in Greenwich Mean Time

**Flask code** - marking of nameplates for each flask

**Flask** - position of flask within the sample row

**site** - location of the flight pattern

Norunda - flight pattern around the Norunda tower north west of Uppsala.  
Coniferous forest: 60°05'N / 17°29'E

Florarna - natural sanctuary of swamps and forests north west of Osterbybruk:  
60°18'N / 17°48'E

Sumpf - ground reference site within the open swamp: 60°18'N / 17°50'E

Forest - ground reference site inside the wooded area: 60°17'N / 17°48'E

**alt** - sampling height in meter above ground, referring to the place of departure

**init p.** - internal flask pressure at the beginning of the analyses

## Mixing ratios

**CH<sub>4</sub> [ppb]** - methane mixing ratio in ppb

**CO<sub>2</sub> [ppm]** - carbon dioxide mixing ratio in ppm

**N<sub>2</sub>O [ppb]** - nitrous oxide mixing ratio in ppb

**CO [ppb]** - carbon monoxide mixing ratio in ppb

**H<sub>2</sub> [ppb]** - hydrogen mixing ratio in ppb

**SF<sub>6</sub> [ppt]** - sulfur hexafluoride mixing ratio in ppt

Precision of the analyses

1.3 ppb

0.08 ppm

0.15 ppb

1.0 ppb

5.0 ppb

0.08 ppt

## Isotope Ratio

$$\delta[\text{\textdollar}] = (R_{\text{sa}}/R_{\text{ref}} - 1) \cdot 1000$$

$R_{\text{sa}}$  and  $R_{\text{ref}}$  are the sample and reference isotope ratios

**del <sup>13</sup>C [\\$]** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del <sup>18</sup>O [\\$]** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

Precision of the analyses <sup>13</sup>C = 0.012 \\$ <sup>18</sup>O = 0.02 \\$

date&time [GMT]	flask code	site	alt [m]	init p.	mixing ratios						isotope	
					CH <sub>4</sub> [ppb]	CO <sub>2</sub> [ppm]	CO [ppb]	H <sub>2</sub> [ppb]	SF <sub>6</sub> [ppt]	N <sub>2</sub> O [ppb]	del <sup>13</sup> C [‰]	del <sup>18</sup> O [‰]

## **Valencia Summer Experiment**

**17 June – 7 July 2001**

### **First experiment with the modified flight sampling system**

The spatial frame of the study region enclosed a coastal plain from the Mediterranean Sea in the East to the slopes of the Iberian Plateau in the West, with an extension of 20 – 30 km. The northern edge was defined by the Lagoon 'Albufera', the southern border was marked by the Júcar River. Very intensive agriculture use characterizes the coastal plain, from east to west: a zone of paddy fields along the shore line passes over to citrus and apricot orchards on the higher parts of the plain, where also the urban settlements are located. Two main roads transect the study area in north-south direction.

Synoptic conditions typical for the region during the campaign: forced by thermal lows over the Iberian Peninsula surface inland winds established during day time with a compensatory large-scale subsidence over the coastal zones, whereas during night time a land-sea circulation developed.

**Figure 1**

Satellite image of the study region. The locations where the vertical profile flights were performed are marked by the yellow arrows.

# Summer Field Campaign

17 June – 7 July 2001

Flight profile samplings: on 25, 26, 28 June / 2, 3 July above the orchards and on 4 July above the ricefields

On 27 June in the late afternoon an additional comparison flight was performed with the MFP 'SkyArrow' parallel to the coast line (VFlug).

Sampling heights: Lowest sampling level was 100 m above ground, the top height differs from 1500 to 2000 m above ground.

Sampling times: Morning flights around 7:00 UTC, midday flights around 10:30 UTC and afternoon flights around 14:30 UTC.

Aircraft: Morane Socata, 160 HP. Single engine, propeller clockwise. Four seat low wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate  $1 \text{ m s}^{-1}$ . Tube inlet mounted at right wing tip, approximately 15 cm beneath the profile bottom, facing downwards to the front.

Ground reference samplings: 3 July 'night time' [3:30 UTC] and 5 July 'day time' [12:00 UTC] in the apricot orchard.

4 July 'day time' [13:00 UTC] above the rice fields.

**Figure 2** Study area dominated by citrus and apricot orchards. The yellow arrow marks the ground reference sampling site. View direction is eastwards to the Mediterranean Sea.

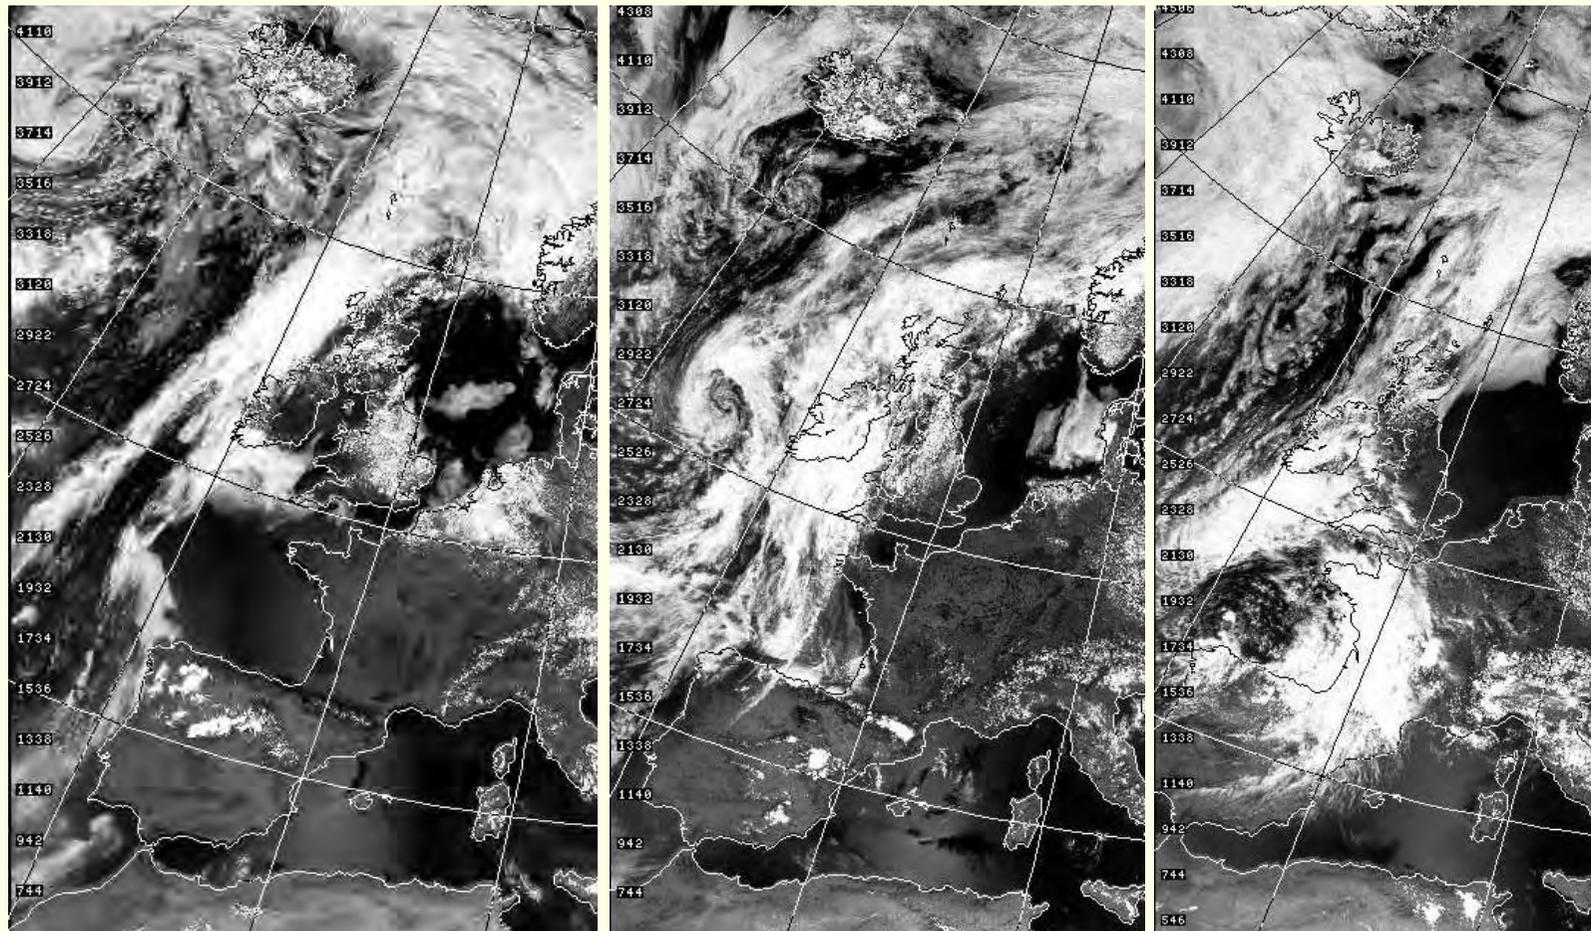

Picture: late afternoon 4 July 2001

**Figure 3** 'Orchard' ground reference site. Upper picture was taken on 5 July 2001, the picture below showing the same spot on 11 December 2001.

**Figure 4** Combustion of green material within the orchards as observed most frequently during the campaign. Flight altitude approximately 300 m above ground.

2 July 2001 13:10 UTC

3 July 2001 12:59 UTC

4 July 2001 12:49 UTC

NOAA 16 Channel 1 (visible 0.58 – 0.68  $\mu\text{m}$ )

# Winter Field Campaign

17 November – 16 December 2001

Flight profile samplings: on 1, 2, 4, 5 and 6 December above the ricefields, and on 12 December above the mountain site.

Sampling heights: Lowest sampling level was 10 m above ground, common used heights were 20, 80, 150, 230 up to 1000 m above ground.

Sampling times: Morning flights around 7:00 UTC, midday around 11:30 UTC and afternoon flights around 14:30 UTC.

Aircraft: Morane Socata, 160 HP. Single engine, propeller clockwise. Four seat low wing airplane. Flight speed during sampling procedure 75 knts (~140 km/h), climbing rate  $1 \text{ m s}^{-1}$ . Tube inlet mounted at right wing tip, approximately 15 cm beneath the profile bottom, facing downwards to the front.

Ground reference samplings: 30 November 'day time' in the orange plantation [12:30 UTC] and above the rice field [15:30 UTC].  
3 December 'night time' above the rice field [4:30 UTC] and in the orange plantation [7:50 UTC].  
13 December 'night time' [7:10 UTC] and 'day time' [13:20 UTC] above the mountain site.  
13 December close to the highway [20:30 UTC].

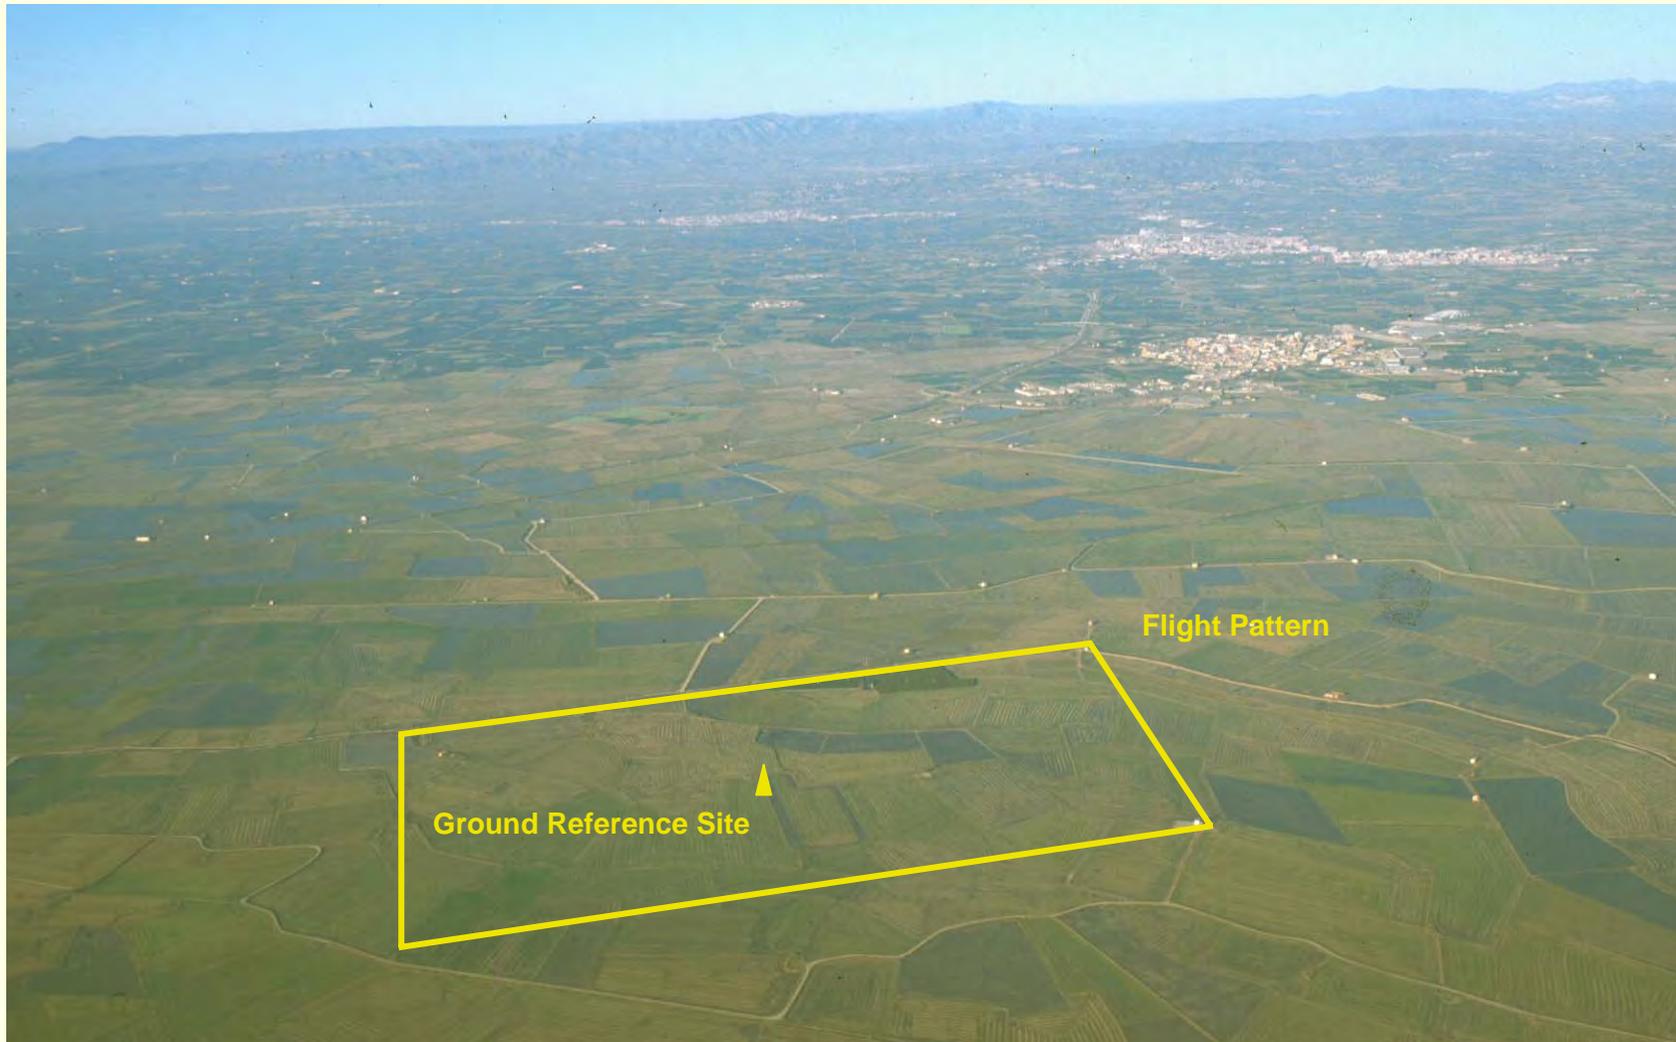

## **Valencia Winter Experiment**

**16 November – 15 December 2001**

### **Final configuration of the modified flight sampling system**

During the campaign a high pressure cell centred above the Iberian Peninsula dominated the weather conditions. Because of clear sky and daily temperatures above 15°C like in summer a land-sea-wind circulation developed, however less intensive and extended than in June and July.

Because of frequent biomass burning activity the orchard site area was this time excluded from flight sampling. Vertical profiles were executed above the rice fields (including one sample taken off shore during the noon flight) and above a mountain site about 50 km inland. The rice fields had been harvested, but uncontrolled growth occurred because heavy rainfalls flooded the fields the weeks before. Additional ground level measurements and samplings were carried out above the rice fields, in a citrus orchard, above the mountain site and close to a highway.

**Figure 6** Flight pattern and location of the ground reference site. View above the Ricefields, the Orchards and the Coast Mountains to the West.

## PARAMETER/VARIABLE DESCRIPTION

**date&time (GMT)** - date and time the sampling procedure was completed in Greenwich Mean Time

**flask code** - marking of nameplates for each flask

**site** - location of the flight pattern / ground reference site

Valzi - south of Valencia above the citrus and apricot plantations  
[39°15.0'N / 000°26.7'W]

Reis - above the paddy fields south of Lake Albufera  
[39°15.8'N / 000°20.6'W]

Mare - around 1 km off shore, east of Tamarital

P-Plant - inside the apricot plantation

Reis-Bo - at the temporary field site in the paddy field

**alt** - sampling height in meter above ground

**init p.** - internal flask pressure at the beginning of the analyses

### Mixing ratios

**CH<sub>4</sub> [ppb]** - methan concentration in ppb

**CO<sub>2</sub> [ppm]** - carbon dioxide concentration in ppm

**N<sub>2</sub>O [ppb]** - nitrous oxide concentration in ppb

Precision of the analyses

1.3 ppb

0.08 ppm

0.15 ppb

### Isotope Ratio

$\delta[\text{\textperthousand}] = (R_{sa}/R_{ref} - 1) \cdot 1000$        $R_{sa}$  and  $R_{ref}$  are the sample and reference isotope ratios

**del <sup>13</sup>C [‰]** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del <sup>18</sup>O [‰]** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

Precision of the analyses    <sup>13</sup>C = 0.012 ‰    <sup>18</sup>O = 0.02 ‰

date&time [GMT]	flask code	site	alt [m]	init p.	mixing ratio			isotope	
					CH <sub>4</sub> [ppb]	CO <sub>2</sub> [ppm]	N <sub>2</sub> O [ppb]	del <sup>13</sup> C [‰]	del <sup>18</sup> O [‰]

## PARAMETER/VARIABLE DESCRIPTION

**date&time (GMT)** - date and time the sampling procedure was completed in Greenwich Mean Time

**flask code** - marking of nameplates for each flask

**site** - location of the flight pattern / ground reference site

Rice - flight track around the temporal CEAM flux tower at the ricefield site south-east of Sollana (Waypoints: NE 39,27874°N / 000,33356°W, NW 39,28093°N / 000,34595°W, SE 39,26414°N / 000,33343°W, SW 39,26694°N / 000,34417°W; Tower for ground reference 39,26453°N / 000,34329°W)

Cortes - flight track above vegetation type of macchie, mountain site, Slightly rolling plateau ~ 750m a.s.l. (Tower for ground reference 39,22550°N / 000,82689°W)

**alt** - sampling height in meter above ground

**init p.** - internal flask pressure at the beginning of the analyses

### Mixing Ratios

	Precision of the analyses
<b>CH<sub>4</sub> [ppb]</b> - methane concentration in ppb	1.3 ppb
<b>CO<sub>2</sub> [ppm]</b> - carbon dioxide concentration in ppm	0.08 ppm
<b>N<sub>2</sub>O [ppb]</b> - nitrous oxide concentration in ppb	0.15 ppb
<b>CO [ppb]</b> - carbon monoxide concentration in ppb	1.0 ppb
<b>H<sub>2</sub> [ppb]</b> - hydrogen concentration in ppb	5.0 ppb
<b>SF<sub>6</sub> [ppt]</b> - sulfur hexafluoride in ppt	0.08 ppt

### Isotope Ratio

$\delta[\text{\textcircled{S}}] = (R_{\text{sa}}/R_{\text{ref}} - 1) \cdot 1000$        $R_{\text{sa}}$  and  $R_{\text{ref}}$  are the sample and reference isotope ratios

**del <sup>13</sup>C [‰]** - ratio of the carbon 13 isotope and carbon 12 isotope due to the VPDB isotope ratio scale

**del <sup>18</sup>O [‰]** - ratio of the oxygen 18 isotope and oxygen 16 isotope due to the VPDB (gas) isotope ratio scale

Precision of the analyses    <sup>13</sup>C = 0.012 ‰    <sup>18</sup>O = 0.02 ‰

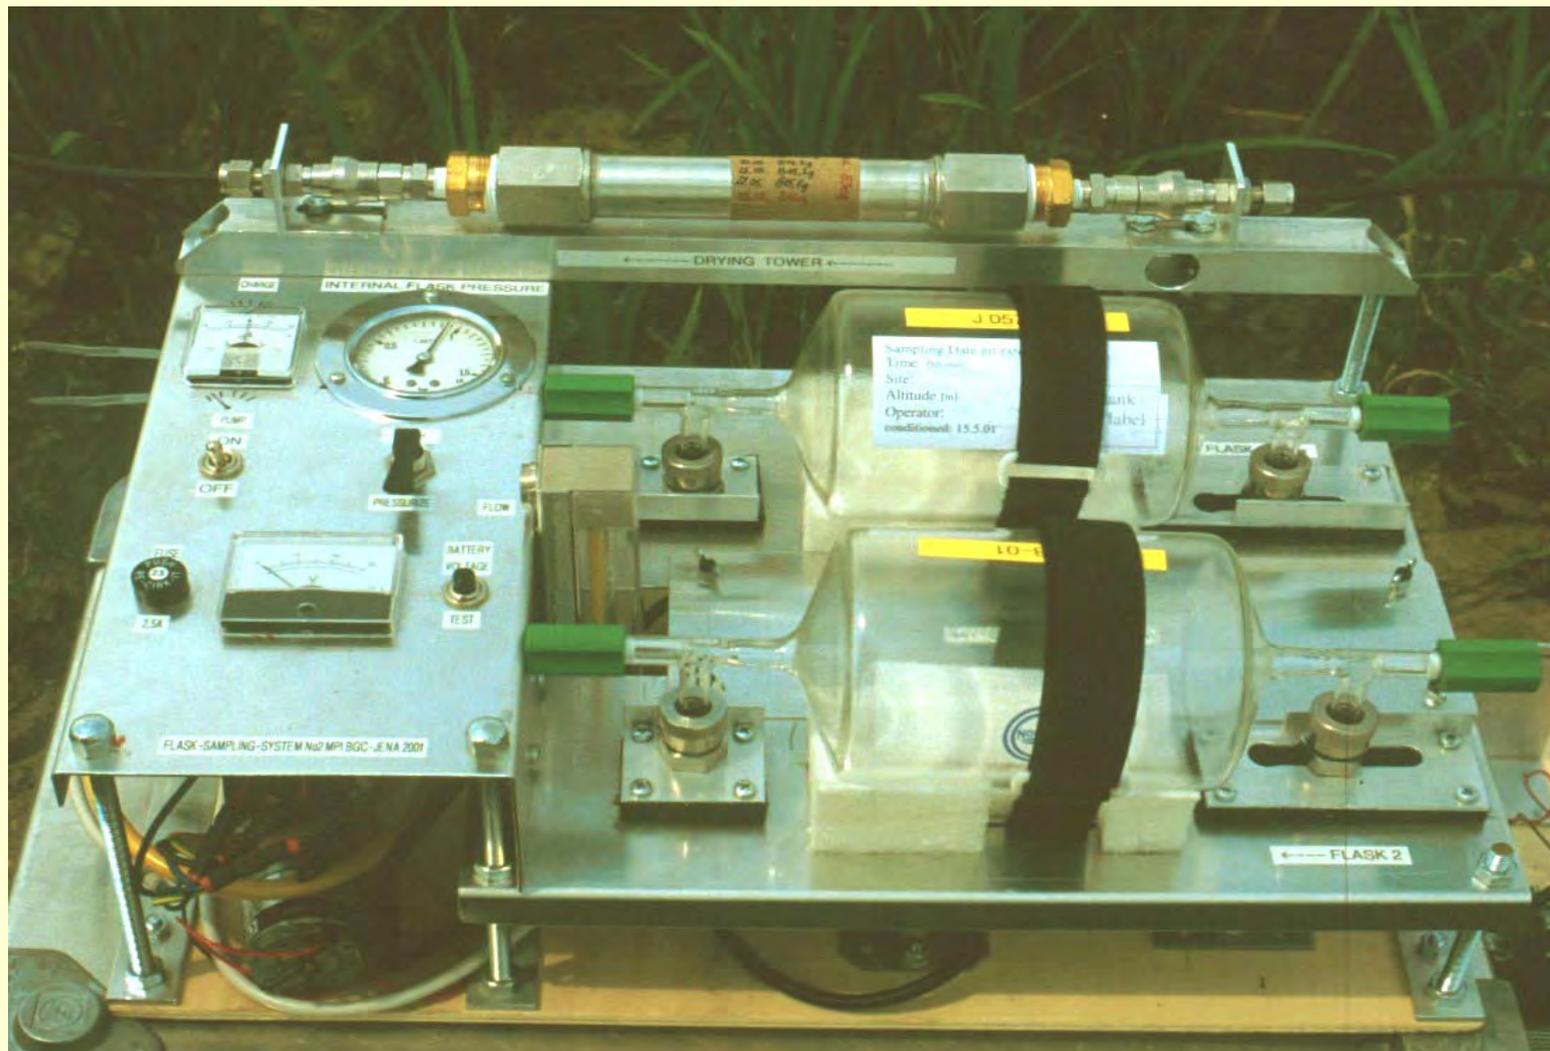

date&time [GMT]	Flask No.	site	alt [m]	init p.	mixing ratio						isotope

**Figure 1** Traditional Flask-Sampling-System of the MPI-BGC with the configuration used within this study until Spring 2001. The original plastic tubes are already replaced by decarbon pipes.

**Figure 2** Traditional Flask-Sampling-System inside the cabin of the WILGA-35 used for the German flights. Notice the horizontal drying column, the tubes as well as the particle filter from plastics and the TAVCO restriction valve.

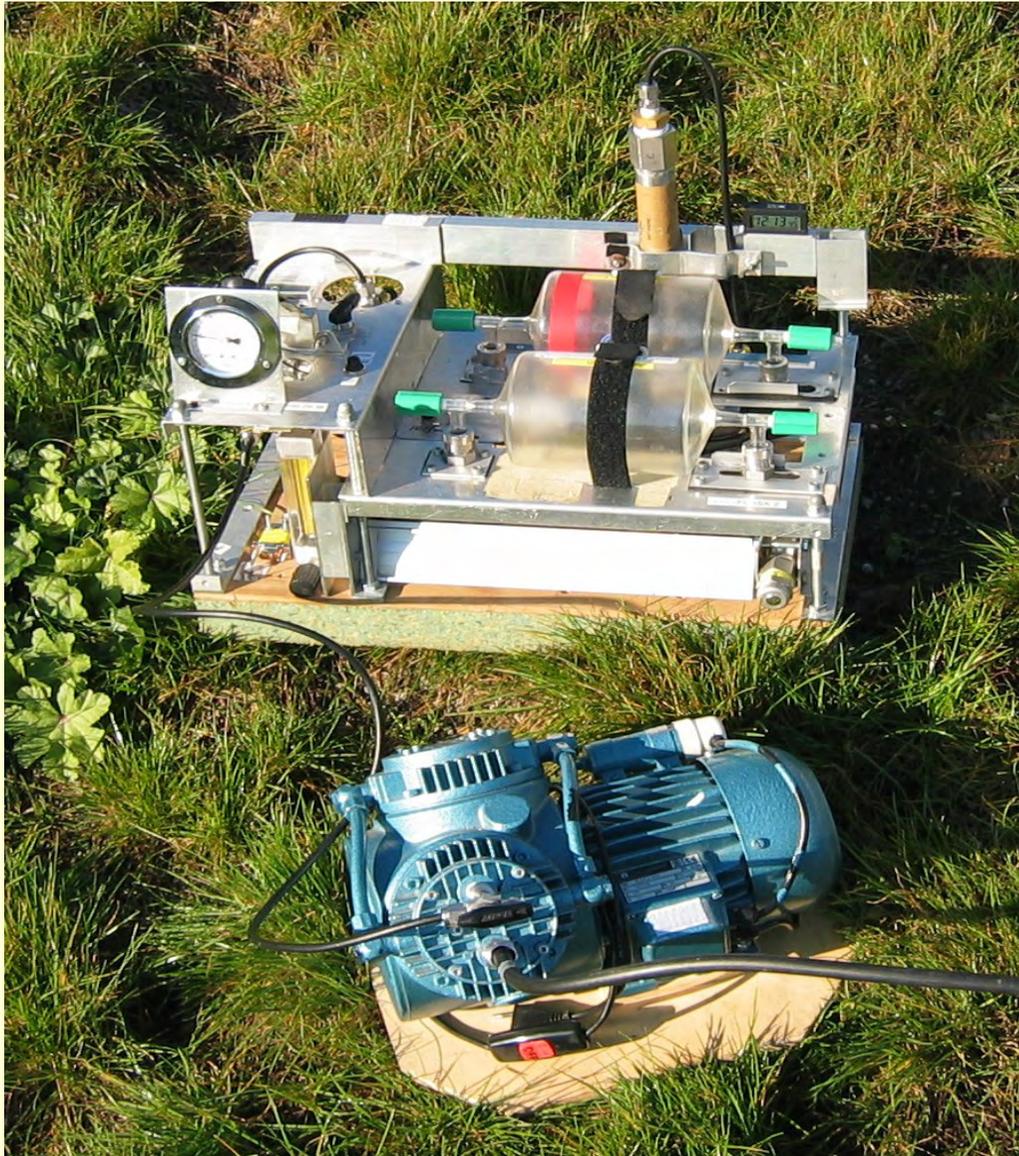

October 2000

## Original flight sampling unit:

½" Teflon® tube (length 650 cm) from wing tip to horizontal drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 65 g] as binder medium (Fluka Chemika) – ¼" Teflon® tube (all lines within the sample unit) – particle filter (Gelman, 1.0 micron) – pump (KNF N 814 KNDC) – unidirectional restrictor valve (Swagelok) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon® PFA O-rings, prefilled with calibration gas of known trace gas concentrations [2 bar abs.] - in and out fixed by ½" Cajon Ultratorr shafts (Swagelok) – 3-way-valve (Swagelok; 1 – in, 2 – out →flushing, 3 – out →sampling);

*for flushing:* – mechanical flow controller (Krohne 0/232939.2) – outlet

*for sampling:* – analog manometer (Empeo, NR63.14 0-2.5 bar) – restriction outlet 2 bar abs (TAVCO, 2391244-8-3)

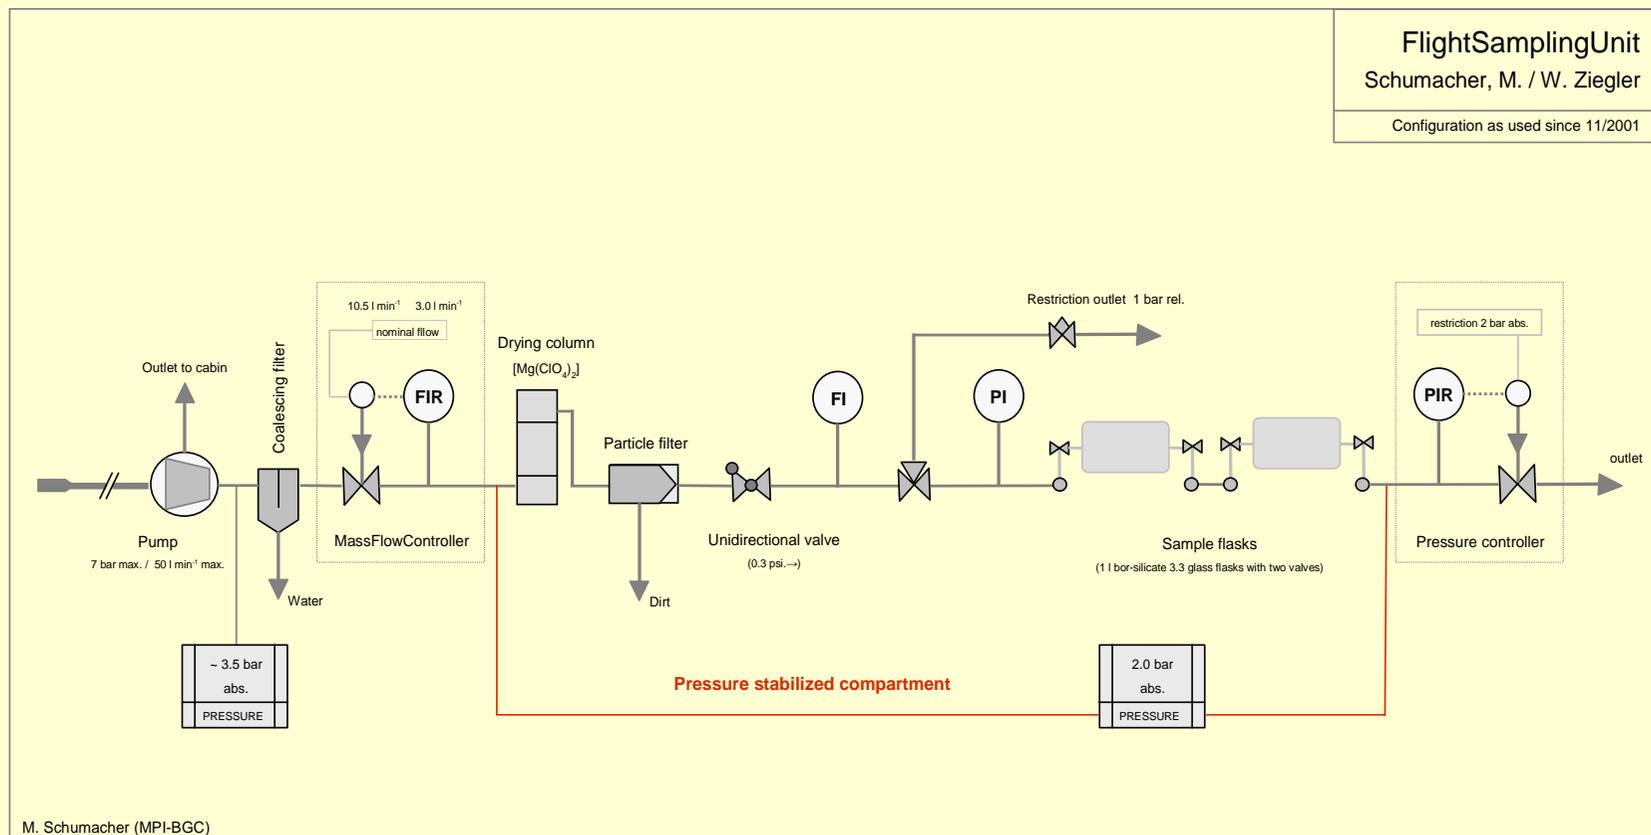

**Figure 3**

Modified Flight Sampling Unit.

Used in this configuration since the Valencia Winter campaign in November 2001.

## Modified Flight Sampling Unit:

½" Decabon® tube (length 650 cm) from wing tip to pump (KNF N 145.1.2.AVE) – ¼" steel tube outlet – 3-way-valve (Swagelok; 1 – pump out, 2 – sample unit, 3 – cockpit) – ¼" Decabon® tube (all lines within the sample unit) - coalescing filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GE-15K-FC-03]) – massflow controller (Bronkhorst F201C-FAC22-V [flushing rate ~10.5 l min<sup>-1</sup>, sampling rate 3.0 l min<sup>-1</sup> at 2 bar abs.]) – vertical drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 70 g] as binder medium (Fluka Chemika) – particle filter (stainless steel NUPRO FC Series [Swagelok] with 0.3 micron filter [GS-15K-FC-03]) – unidirectional restrictor valve (Swagelok) - mechanical flow controller (only for control purpose, Krohne 0/232939.2) – 3-way-valve (Swagelok; 1 – in, 2 – out →sample unit, 3 – out →restriction outlet 1 bar rel. [Swagelok RL4 (0.7-15bar)]) – analog manometer (Empeo, NR63.14 0-2.5 bar) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon® PFA O-rings, prefilled with calibration gas of known trace gas concentrations [2 bar abs.] - in and out fixed by ½" Cajon Ultratorr shafts (Swagelok) – pressure controller (Bronkhorst P702C-FAC-22-V; restriction 2 bar abs.)

**Figure 4** Configuration of the modified FlightSamplingUnit. Operated in this configuration since the Valencia Winter Experiment 2001.

**Figure 5** Installation of the flight equipment at the Montorotondo Airfield in Italy. Location of the air inlet was on the right wing tip. The tube is covered by the wing nose, becoming visible at the white taped section. Aircraft is a Morane Socata.

**Figure 6** Pump and power supply installed at the copilots place inside the cabin.

**Figure 7** FlightSamplingUnit, GPS (on the barrier between front and rear seat), switch box of the continuous measurement system in front of the GPS. Laptop for system controlling and data recording – during the flight fixed on the operators thigh. Sample flasks are stored in the rear of the cabin Recognizable are on the left wing the mounted sensors for air temperature and humidity, dynamic and static pressure and the compass module.

## Instrumentation – Ground Sampling and Reference System

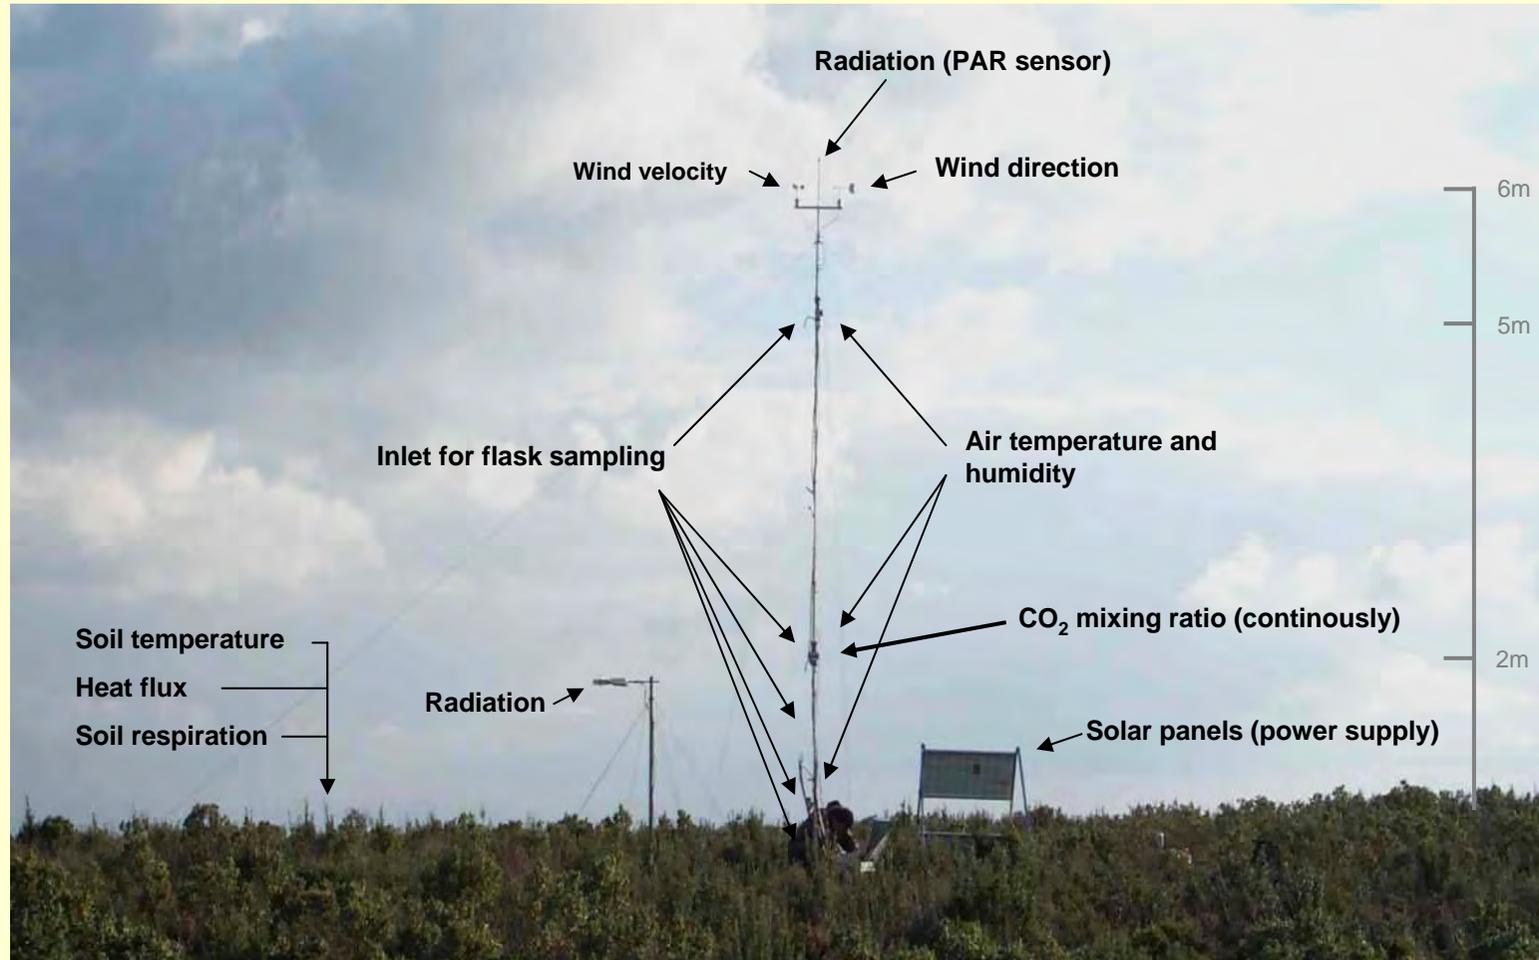

- Figure 1            Flask Sampling System  
                          Description of the Ground Sampling System
- Figure 2            Instrumentation of the Ground Reference System (6 m light weight mast construction)

**Figure 1** Flask Sampling System used for the ground reference sampling.

Ground sampling system:

½" Decabon® tube from mast to pump unit (two pumps in row: KNF N 828 KNDC & KNF N 814 KNDC) – ¼" Decabon® tube (all lines within the sample unit) – horizontal drying column (stainless steel) with Mg(ClO<sub>4</sub>)<sub>2</sub> [~ 65 g] as binder medium (Fluka Chemika) – particle filter (Gelman, 0.3 micron) – mechanical flow controller (Krohne 0/232939.2) – unidirectional restrictor valve (Swagelok) – analog manometer (Empeo, NR63.14 0-2.5 bar) – sample flasks (1 l bor-silicate 3.3 glass flasks [Schott], with two valves [Glas Expansion, Australia] sealed with Teflon® PFA O-rings, prefilled with calibration gas of known trace gas mixing ratio [2 bar abs.] - in and out fixed by ½" Cajon Ultratorr shafts (Swagelok) – restriction outlet 1 bar rel. (Swagelok RL4 (0.7-15bar))

**Figure 2** Instrumentation of the ground reference system.

Picture taken at the mountain site 'Cortes des Pallás', December 2001
