Lung function in asbestos-exposed workers, a systematic review and meta-analysis

Dennis Wilken, Marcial Velasco Garrido, Ulf Manuwald and Xaver Baur*

Abstract

Background: A continuing controversy exists about whether, asbestos exposure is associated with significant lung function impairments when major radiological abnormalities are lacking. We conducted a systematic review and meta-analysis in order to assess whether asbestos exposure is related to impairment of lung function parameters independently of the radiological findings.

Methods: MEDLINE was searched from its inception up to April 2010. We included studies that assessed lung function parameters in asbestos exposed workers and stratified subjects according to radiological findings. Estimates of VC, FEV₁ and FEV₁/VC with their dispersion measures were extracted and pooled.

Results: Our meta-analysis with data from 9,921 workers exposed to asbestos demonstrates a statistically significant reduction in VC, FEV₁ and FEV₁/VC, even in those workers without radiological changes. Less severe lung function impairments are detected if the diagnoses are based on (high resolution) computed tomography rather than the less sensitive X-ray images. The degree of lung function impairment was partly related to the proportion of smokers included in the studies.

Conclusions: Asbestos exposure is related to restrictive and obstructive lung function impairment. Even in the absence of radiological evidence of parenchymal or pleural diseases there is a trend for functional impairment.

Keywords: Asbestos, lung function, chest X-ray, computed tomography, meta-analysis

Introduction

Asbestos fibres are one of the most pervasive environmental hazards because of their worldwide use in the last 100 years as a cheap and effective thermal, sound and electrical insulation material, especially in the construction, shipping and textile industries. The general public is also exposed to asbestos, mainly from deterioration and reconstruction or destruction of asbestos contaminated buildings, worn vehicle brake linings and from the deterioration of asbestos-containing products. In spite of outright bans or restrictions in nearly all industrialised countries nowadays, approximately 125 million workers are occupationally exposed to asbestos worldwide [1] and it is estimated that at least 100,000 die annually from complications of asbestos exposure [2]. In addition to mesothelioma, lung and laryngeal cancer, asbestos has long been known to cause non-

malignant pleural fibrosis, (i.e. circumscribed pleural plaques (PP), or diffuse pleural thickening (DPT)), pleural effusions, rounded atelectasis and lung fibrosis (asbestosis). Since inhalation of high doses of asbestos fibres may lead to a variety of functional impairments, the monitoring of workers who have been exposed to asbestos, particularly of their lung function, has gained in importance over the years. The identification of functional abnormalities is also relevant for compensation issues. While compromised lung function in pronounced disease is widely accepted, controversies still remain about a possible relationship between earlier or milder non-malignant asbestos-induced pleural or parenchymal fibrosis and reduced lung function measurements [3-11]. The American Thoracic Society and the American College of Chest Physicians [12,13], in particular, have lamented the lack of definitive knowledge in the prevalence and clinical relevance of asbestos-induced obstructive airway diseases and have determined to make this a priority for investigation and elucidation.

Institute for Occupational and Maritime Medicine, University Medical Center Hamburg-Eppendorf, Hamburg, Germany

We have conducted a systematic review and a meta-analysis of the literature with the aim of identifying and quantifying alterations of lung function parameters in subjects occupationally exposed to asbestos. The leading question was whether occupational exposure to asbestos leads to impairments of lung function independently from the non-malignant radiological findings (i.e. normal chest radiograph (X-ray) or (high resolution) computed tomography (HR)CT, pleural plaques and diffuse pleural thickening or asbestosis).

Materials and methods

Selection criteria

We included publications that assessed lung function parameters and radiological imaging (chest X-Ray or (HR)CT) in persons with occupational exposure to asbestos. Only studies that applied an internationally accepted quality standard for lung function testing (i.e. ATS standard, ERS standard) and that provided information about the corresponding reference values or used reference group were considered. We included only studies reporting lung function parameters expressed as percent-predicted with a corresponding dispersion measure (i.e. standard deviation, standard error or confidence interval) and assigned them to one of the following radiological categories:

- A. "Normal imaging", i.e. absence of pleural or lung parenchymal abnormalities.
- B. "Pleural fibrosis", i.e. presence of pleural plaques and/or diffuse pleural thickening.
- C. "Asbestosis", i.e. parenchymal fibrosis with or without pleural fibrosis.

To be included, studies had to provide data on the proportion of smokers among participants or on the dose (pack-years).

In a few potentially relevant studies the authors failed to report all information listed above (e.g. reference values, quality standards, dispersion measures), thus we tried to contact the authors in order to collect the missing data. Only three authors sent additional information that enabled us to include their publication in the meta-analysis.

Search strategy

MEDLINE was searched from its inception to April 2010 via PubMed with the following search strategy:

("Asbestosis"[Mesh] OR ("Pleural Diseases"[Mesh] AND "Asbestos"[Mesh]) OR ("occupational exposure"[Mesh] AND "Asbestos"[Mesh]) OR ("Lung diseases"[Mesh] AND "Asbestos"[Mesh])) AND "Respiratory Function Tests"[Mesh] AND ("occupational diseases"[Mesh] OR "occupational health"[Mesh] OR "occupational exposure"[Mesh])

We applied the following PubMed limits in order to increase the specificity of our search:

("humans"[MeSH Terms] AND (English[lang] OR German[lang])) AND "adult"[MeSH Terms]) NOT ("Bronchoalveolar Lavage"[MeSH] OR "Neoplasms"[-Mesh] OR "Case Reports" [Publication Type]).

Additionally, we scanned congress proceedings, reference lists of relevant articles and searched our own archive for further potentially relevant publications not identified through the electronic search.

Data extraction

We extracted information on sample size, exposure to asbestos, proportion of non-smokers, radiological imaging method and lung function reference values together with the estimates for vital capacity (VC), forced expiratory volume in the first second (FEV₁) and FEV₁/VC with their corresponding SD, SE or 95% CI. Most of the studies reported forced vital capacity (FVC), but in some papers it was not clear whether FVC or slow (relaxed) vital capacity (SVC) was measured. Data were extracted by at least two of the authors independently from each other and discrepancies were solved by consensus after discussion. (HR)CT-based diagnoses were favoured over those based on X-rays when both were available.

Data synthesis and statistical methods

We performed a meta-analysis to produce pooled estimates of VC, FEV₁ and FEV₁/VC for each of our designated radiological categories (A, B or C). Within each radiological category, we conducted subgroup analysis according to the type of imaging method used for the diagnosis (X-ray or (HR)CT).

Some studies reported results for different degrees of radiological impairments within the same category (e.g. different ILO scores for asbestosis). In these cases, we pooled the subgroup estimates from the same study with a fixed effects model to obtain a single estimate for each study within each radiological category (A-C).

A random effects model was used to calculate overall estimates for each radiological category.

We calculated I² as an indicator for the degree of heterogeneity across studies. Values of I² under 25% indicate low, up to 60% medium and over 75% considerable heterogeneity, making it advisable to perform the analysis using the random effects model [14]. In order to assess whether any observed between-study heterogeneity could be explained through study characteristics other than radiological imaging procedure, we also performed subgroup analysis for the proportion of never-smokers. For this purpose, we divided the study pool into two categories: studies with <25% of participants reporting to have never-smoked and studies with >= 25% of participants reporting to have never-smoked.

A second subgroup analysis was done for mean duration of asbestos exposure, dividing the study pool into two categories: studies reporting mean exposure duration longer than the median duration of the whole sample vs. studies with mean exposure duration shorter than median duration. In addition, we performed meta-regression analysis with the proportion of never-smokers and with the years of asbestos-exposed occupation.

All calculations were performed with the software Comprehensive Meta-Analysis 2.0. (Biostat™, Englewood, USA). Forest plot graphics were produced with Meta-Analyst Software [15]

Results

A total of 542 papers were identified by the electronic literature database search and a further 46 papers through manual searching in congress reports, reference scanning and from our own archive (Figure 1). After scanning titles and abstracts, 289 articles were selected for a detailed assessment of the full publication. From these 289 articles, 30 met the inclusion criteria for the meta-analysis. The most frequent reasons for exclusion were lack of information about lung function parameters and/or about radiological diagnoses and lack of reporting statistical dispersion measures.

We included 27 cross-sectional studies, one case-control and two follow-up studies, comprising a total of 15,097 subjects of which the data for 9,921 were reported appropriately for inclusion in our meta-analysis. The characteristics of the included studies are shown in Table 1. Sample size ranged from 19 to 3,383. Some studies focussed on a specific occupation (e.g. asbestos manufacturing, insulation and cladding work, shipyard, asbestos industries, asbestos cement factory, ceiling tiles and wallboards, railway, ironworker, sheet metal, construction carpenters and millwrights) while others included subjects from different occupational fields. The mean duration of occupational exposure to asbestos was reported in 22 studies (i.e. 73% of the study sample) and ranged from 8.4 ± 6.1 to 32.7 ± 6.7 years (mean \pm SD). The latency time (i.e. the time since first exposure) was reported in only 9 studies (i.e. 30%) and ranged from 24.5 ± 5.7 to 43.3 ± 6.7 years (mean \pm SD). Estimations of asbestos fibre concentration (i.e. fibre-years) were reported only rarely [16,17].

Except for two studies [18,19], all included current and/or former smokers. The proportion of participants reporting to be never-smokers ranged across the studies from only 3% to 100% (median 26.2%), with three studies not reporting the proportion of never-smokers. Smoking severity was reported in 18 of the studies that included smokers and ranged from 14.0 ± 11.9 to 38.9 ± 29.4 pack-years (mean \pm SD).

Radiological imaging was done relying exclusively on chest X-ray in 15 studies and relying exclusively on CT or HRCT in 7 studies. Eight studies considered both chest X-ray and CT/HRCT. Mainly VC, FEV₁ or FEV₁/VC, or combinations of these parameters, were reported. Some studies provided additional parameters, but due to their scarcity and heterogeneity in assessment methods we did not include them in the meta-analysis. In all studies, lung function test results were acquired according to a quality standard, with the majority (67%) following the American Thoracic Society (ATS) standard procedure available at the time. There was considerable heterogeneity regarding the reference values used to calculate "percent of predicted", with a total of 12 different reference values used across the included studies. The most frequently used reference values were those proposed by Quanjer 1983/1993 [20,21] (n = 5 studies), followed by those of the ATS [22] and Knudson 1983 [23] (both in 4 studies each).

Quantitative data synthesis

Figures 2, 3 and 4 provide an overview of the pooled estimates of lung function parameters according to radiological findings.

Vital capacity

Vital capacity (VC, FVC) was the parameter most commonly reported in an adequate manner for inclusion in our meta-analysis. Overall, asbestos-exposed workers showed an impairment of vital capacity when compared with reference values (Figure 2). This impairment of vital capacity was already manifest in workers without radiological evidence of asbestos-related pleural or parenchymal diseases (95.7%-predicted; 95%-CI 93.9, 97.3). The loss of vital capacity was most accentuated in subjects with radiological findings of asbestosis (86.5%-predicted; 95%-CI 83.7, 89.4). The subgroup analysis based on the radiological procedure showed lower estimates of vital capacity in all three radiological categories among studies using conventional chest X-ray compared with those using (HR)CT (Table 2).

Heterogeneity was very high in all three radiological subgroups ($I^2 > 90\%$) and remained after subgroup analysis according to radiological procedure.

FEV₁

As for vital capacity, asbestos-exposed workers showed an impairment of FEV₁ which was already present in workers with no radiological evidence of asbestos-related disease and was considerably more pronounced in subjects with radiological signs of asbestos-related pleural and/or parenchymal diseases (Figure 3). Again, the subgroup analysis showed differences between studies using chest X-ray and studies using (HR)CT (Table

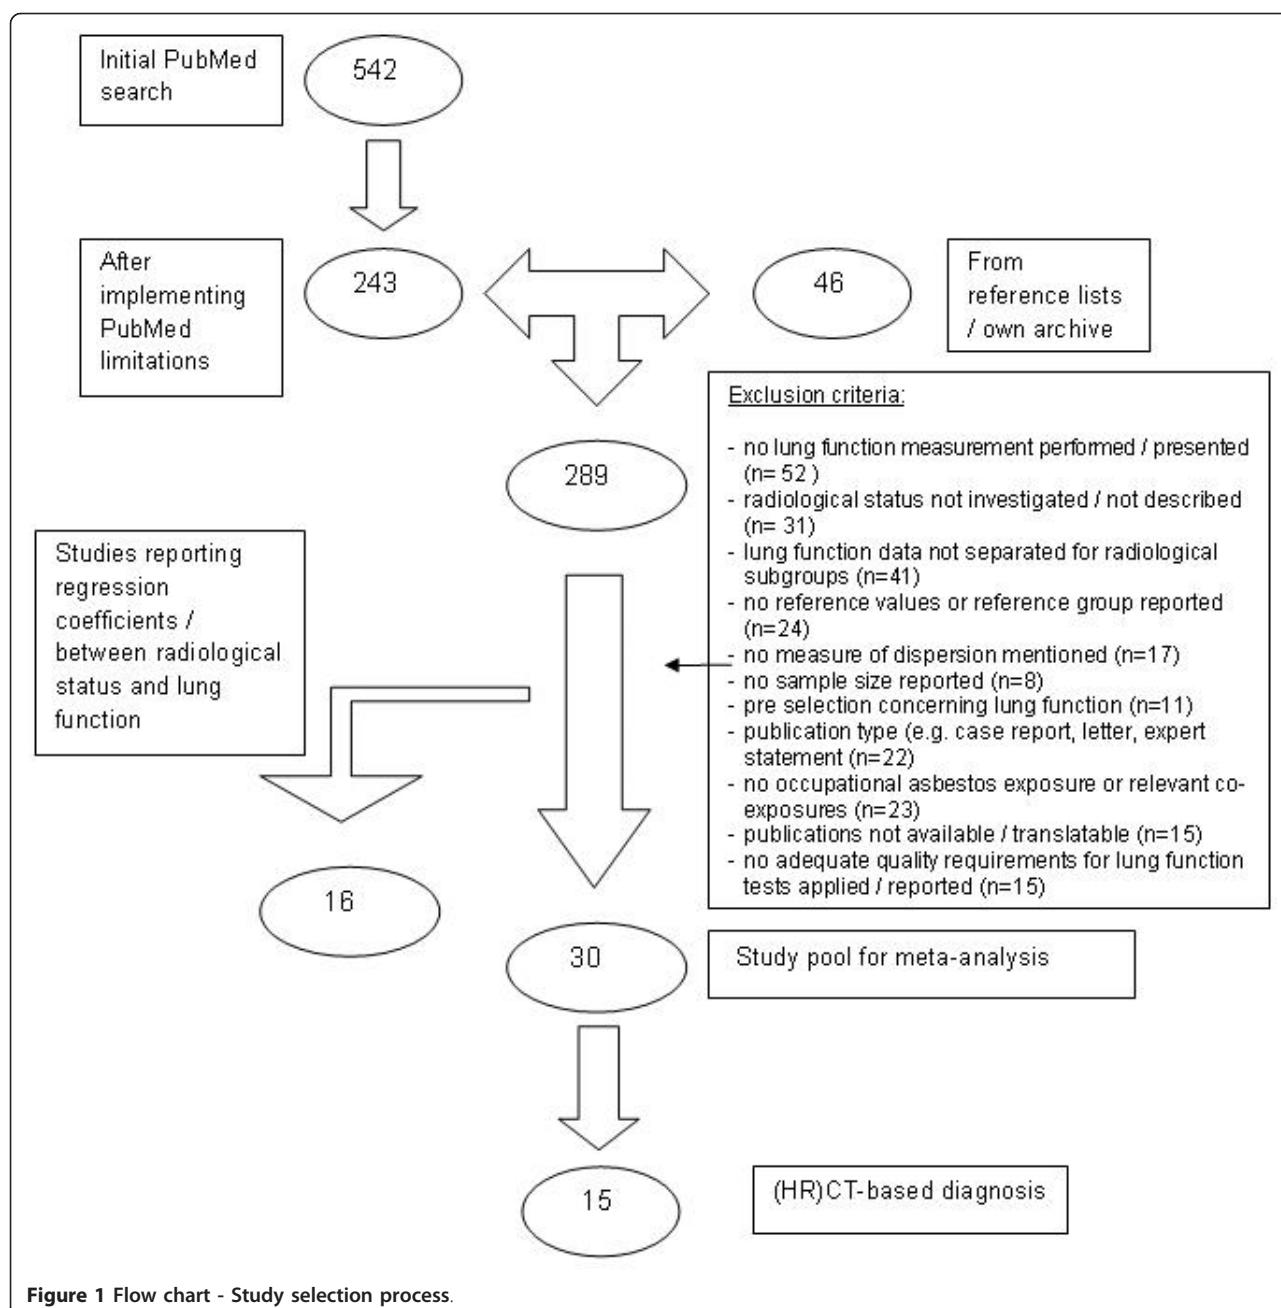

Figure 1 Flow chart - Study selection process.

2). The differences between both imaging procedures were particularly pronounced for subjects identified as having asbestos-related pleural disease. For this group of patients, the estimate of FEV₁ obtained from the subgroup of studies using conventional X-ray was about 10 percent lower than estimate obtained from HR(CT) studies (83.9%-predicted; 95% CI 77.2, 90.5 vs. 93.7%-predicted; 95% CI 87.6, 99.9) (Table 2).

Heterogeneity was also very high for these analysis ($I^2 > 90\%$), but decreased to some extent when grouping studies according to radiological technique.

FEV₁/VC

FEV₁/VC was less commonly reported in an adequate manner for inclusion in our analysis. Slight FEV₁/VC reductions were already seen in workers even without radiological signs of disease, and were similar to those seen for workers with evidence of pleural disease and for those with signs of lung fibrosis related to asbestos (Figure 4). As for the other lung function parameters, there were differences between studies according to the radiological method used, with a tendency to lower FEV₁/VC among the studies using chest X-ray.

Comparison of imaging procedure.

Estimates for forced vital capacity (FVC), forced expiratory volume in the first second (FEV1) and the ratio of both parameters (FEV1/FVC) for each radiological subgroup. Results are shown for all included studies as well as separated according to the radiological method used for the diagnosis (conventional chest X-ray or (high resolution) computed tomography. Estimates are expressed as percent predicted together with confidence interval (CI) and I² as a measure of heterogeneity, n = number of studies included in each subgroup.

Heterogeneity was considerable ($I^2 > 60\%$) but not as pronounced as for the other lung function parameters.

Subgroup analysis and meta-regression

Smoking

Few studies reported estimates stratified by smoking status and radiological category. The proportion of never-smokers was reported in 27 studies. The lung function estimates derived from the subgroup analysis showed greater impairment among studies with more than 25% of participants reporting to be never-smokers for subjects without radiological evidence of asbestos-related

disease and in those with pleural fibrosis (Table 3). In the group of workers showing radiological evidence of asbestosis lung function impairments were strongest and a bit more pronounced in the subgroup of studies with a lower proportion of never-smokers.

In the regression analysis of the effect of the proportion of non-smokers on estimates of FEV₁, those studies with a higher proportion of never-smokers tended to show less impairment of this parameter (not statistically significant) for all three radiological categories.

Table 4 shows the results of three studies [24-26] reporting estimates for non-smokers and smokers

Table 3 Estimates of lung function according to radiological findings

	Overall				Studies with <25% non-smokers				Studies with >25% non-smokers

Subgroup analysis according to % of never-smokers.

Estimates for forced vital capacity (FVC), forced expiratory volume in the first second (FEV1) and the ratio of both parameters (FEV1/FVC) for each radiological subgroup. Results are shown for all included studies as well as separated according to the proportion of non-smokers included in each subgroup (less or more than 25%). Estimates are expressed as percent predicted together with confidence interval (CI) and I² as a measure of heterogeneity, n = number of studies included in each subgroup.

Table 4 Asbestos-exposed workers without radiological evidence of parenchymal disease stratified by smoking status

Studie	Non-smokers			Smokers		
	n	% predicted	SD	n	% predicted	SD
Hall 1982	FEV ₁	46	101.0	13.6	67	92.5
	FVC		102.2	11.6		99.2
Neri 1996	FEV ₁	34	90.9	15.6	47	92.0
	FVC		89.7	14.9		90.9
	FEV ₁ /FVC		100.3	10.9		100.2
Oldenburg 2001	FEV ₁	12	105.7	13.6	31	83.6
	FVC		96.1	10.9		86.7
	FEV ₁ /FVC		102.3	4.39		94.5

Differences in forced vital capacity (FVC), forced expiratory volume in the first second (FEV₁) and the ratio of both parameters (FEV₁/FVC) between asbestos exposed non-smokers and smokers without radiological evidence of asbestosis. Estimates expressed as percent predicted together with standard deviation (SD) and I² as a measure of heterogeneity, n = number of subjects included in each subgroup.

without radiological evidence of parenchymal disease. These papers suggest mainly a synergistic effect of smoking and asbestos exposure.

Duration of asbestos exposure

Mean exposure duration was reported in 23 studies. The data was heterogeneous (Table 5). FEV₁ was consistently better across all radiological categories in the subgroup of studies with a mean exposure length of more than 22 years. In contrast, FEV₁/VC was consistently better across all radiological subgroups for the studies with shorter mean exposure duration. The results for FVC were inconsistent. The regression analysis, however,

indicated that lower FVC and FEV₁ could be expected with increasing mean exposure duration.

Discussion

Several population-based studies provide evidence of asbestos exposure contributing significantly to the burden of airway diseases, but a detailed assessment of exposure was generally neither presented nor performed in such studies [27-29]. The pleural plaque incidence in the general population is in the range of 0.02 to 12.8% [30] and is 80-90% attributable to asbestos exposure [31]. The initial concern about the potential adverse effects of asbestos on lung function was vindicated in clinical as well as epidemiologic studies over many years [12,13]. The present meta-analysis has considered the major lung function parameters VC, FEV₁, FEV₁/VC, for asbestos-exposed workers grouped, according to their radiological diagnosis, into three groups: "absence of pleural and lung parenchymal fibrosis", diagnosed with "pleural fibrosis" (PP and/or DPT) or "asbestosis with or without pleural fibrosis". Overall, our analysis shows a statistically significant reduction of VC, FEV₁ and FEV₁/VC among workers exposed to asbestos compared to the general population (i.e. reference values).

The severity of the observed impairments is related to the degree of radiological abnormalities indicative of pleural fibrosis and asbestosis. Overall, VC and FEV₁ scores were lowest for those workers showing radiological findings of asbestosis, followed by those with signs of pleural fibrosis. Workers exposed to asbestos with normal radiological findings (either X-ray or (HR)CT) exhibited significantly better VC and FEV₁ scores than those with radiological abnormalities, but their decreased values indicate some degree of lung function

Table 5 Estimates of lung function according to radiological findings

Subgroup analysis by mean exposure duration.

Differences in forced vital capacity (FVC), forced expiratory volume in the first second (FEV₁) and the ratio of both parameters (FEV₁/FVC) between subgroups with a mean exposure duration of less (<22 yr.) and more for than 22 years (>22 yr.). Results are shown for each radiological subgroup. Estimates are expressed as percent predicted together with confidence interval (CI) and I² as a measure of heterogeneity, n = number of studies included in each subgroup.

impairment. FEV₁/VC was slightly reduced in all groups. This reduction was more evident in the subgroups with radiological abnormalities. These differences between groups persisted mostly when the studies were analysed separately, according to the radiological methods used (either X-ray or (HR)CT), although less pronounced for the (HR)CT-based studies of the three subgroups of patients. In general, studies with (HR)CT based diagnosis report milder lung function impairments than those using conventional X-ray due to the higher sensitivity of the (HR)CT for mild grades of pleural disorders and asbestososis.

A positive relationship between the severity of functional impairment and the radiologically defined degree (score) of asbestos-related pleural and/or pulmonary fibrosis was already reported in a few studies [32-34]. As shown the absence of characteristic radiological findings does not exclude lung function abnormalities. Our meta-analysis revealed statistically significant deterioration in the lung function parameters for asbestos workers without any evidence of radiological abnormalities. These findings extend the meta-analysis by Filippelli, Martines et al [35] who found statistically significant reductions in all investigated lung function parameters in subjects exposed to asbestos, although the authors did not account for different radiological findings. Regression models reported in some of the included studies indicate that the radiological findings can only explain a small part of the variability in these parameters. Other authors have also reported a medium to low explanatory power of radiological findings for other lung function parameters [33,32].

There is evidence from clinical studies that discrepancies between lung function and radiological findings can be due to asbestos-induced pulmonary alterations not radiologically detectable. These studies describe multiple cellular lesions, apoptosis, inflammatory and profibrogenic responses, using histopathology and electron microscopy, as well as the synthesis of associated mediators and oxygen radicals [36-40]. It has been estimated that exposure to an asbestos fibre dose [41] of 25 fibre-years represents the inhalation of about 55 billion asbestos fibres [42], of which a significant proportion is deposited in the lung.

Our findings indicate not only the presence of restrictive but also of obstructive ventilation patterns in workers exposed to asbestos, either with or without asbestos-related radiological abnormalities: an issue of controversial discussion.

Recently, Dement et al. [43] found an overall COPD prevalence of 18.9% in asbestos workers/insulators. In their collective of older construction and trade workers, at the US Department of Energy with mixed exposure at nuclear sites, the prevalence of COPD was of 23%

among those only with pleural changes and 32.3% among those with both pleural and parenchymal changes [43]. Conversely, Ameille et al. [44] reported a lack of association between occupational exposure to asbestos and airway obstruction. They determined that FEV₁/FVC and FEV₂₅₋₇₅ did not differ through the cumulative exposure classes and there was no significant correlation between cumulative exposure to asbestos and pulmonary function parameters nor with the proportion of abnormal pulmonary function tests [44]. However, these authors did not include a non-exposed control group and report generally elevated values for FVC, FEV₁, FEV₁/FVC and residual volume (RV), which can be explained by the selected study population (volunteers for a screening programme without previous severe respiratory disease).

Bias and limitations

The degree of lung function impairment may have been underestimated due to bias in the included studies. Two main sources of not negligible underestimation of adverse health effects in actual occupational cohort studies are the dilution effect and the comparison bias [45]. The dilution effect results from the inclusion of not or very low exposed workers in the study cohort. The comparison bias results from a healthy hire effects at the beginning of exposure history. The lung function of blue collar workers - like the ones included in our study - is typically better than the references taken from the general population (i.e. over 100% predicted) [46,47]. In those workers lung function values studied at a single time point may be still within the norm despite an underlying considerable absolute decrease since the start of exposure (e.g. a FEV₁ fall from 115% to 95%). Comparison bias results also from the healthy worker effect in the course of the working life. Subjects with relevant health impairments may change their occupation or have a shortened work life and thus may not be available for recruiting to later lung function assessment based on occupation or worksite. For example Fell et al. [48] hypothesized in their investigation on respiratory symptoms and ventilatory function of workers exposed to cement dust that individuals susceptible to adverse respiratory effects from cement dust may have quitted work and therefore dropped out of the exposed groups. The authors found a high prevalence (55%) of respiratory symptoms and COPD in the group of former cement workers visited at home, underlying the importance of included former workers. These biases are probably present in the studies included in our systematic review, since most of them had a cross-sectional design not accounting for changes in lung function over time and in general did not consider former workers.

In our meta-analysis, there is a high degree of heterogeneity (high I^2) across the studies, which we acknowledged by using a random effects model. Heterogeneity is caused by variations in the individual study populations as well as differences in study methods.

With respect to the study design, a major source of heterogeneity is the quality of lung function tests and the variety of references values used in the studies. We included predicted values, as given by the various authors with their considerable variation. For example, the reference values of Quanjer et al. [20,21] have been shown to be at least 10% too low for current normal populations [49-53], thus leading to an underestimation of the effects of asbestos exposure. The same is true for some other reference values based on inadequate reference populations.

The issue of the study population as a source of heterogeneity includes the following aspects: First, studies differed considerably in the duration of occupational exposure to asbestos, ranging from less than 1 year to over 30 years. The subgroup analysis indicated that the results for FEV_1 and for FEV_1/VC were negatively related to the duration of exposure. The meta-regression analysis indicated an inverse relationship between exposure duration and FVC and FEV_1 (i.e. lower estimates with increasing mean exposure duration). However, this can only explain a small amount of heterogeneity. There are also major differences between studies regarding the intensity of exposure because of the wide variety of tasks and occupations studied. Since only two studies [41,54] reported an estimation of exposure intensity (i.e. fibre-years), we could not explore this source of heterogeneity in subgroup or regression analysis. Similarly, mean latency times were only reported in nine of the included studies, thus subgroup analysis or meta-regression to explore heterogeneity could not be performed.

An additional source of heterogeneity may be the differences in the distribution of confounders, such as smoking or co-exposure to other occupational noxae. Regarding co-exposures most of the studies provided little information and we could not explore this potential source of heterogeneity in detail.

An important question concerns the interaction between smoking and asbestos exposure. Only a few studies accounted for smoking in their analysis appropriately. In one of the two studies that included only never-smokers [18], reduced VC was reported for both asbestos-exposed workers without and with pleural fibrosis, and an impairment of FEV_1 was seen in those with pleural fibrosis. The other study considering only never-smokers examined patients with asbestosis. Here all lung function parameters were correspondingly impaired [19].

Niebecker and colleagues showed for patients with asbestosis that the degree of impairment was greater among smokers [9]. Some of the included studies [16,33,55-61] reported multivariate linear regression models including smoking as an explanatory variable (among others). The results of these analyses suggest an association of lung function impairments with pleural abnormalities independent of smoking, i.e. when pleural fibrosis is present then impairments in lung function can be observed in both smokers and non-smokers.

At the study level, the results of subgroup analysis according to the proportion of never-smokers were inconsistent and partly counterintuitive, since for some parameters, the higher the proportion of non-smokers in a study, the lower were the estimates. An additional analysis using the mean pack-years - as an indication of the dose - was not performed, because one third of the included studies did not report the information.

Therefore our approach does not allow a clear differentiation of smoking effects from those of asbestos, mainly due to the shortcomings or the failure to report findings of the included studies but provides evidence that the observed impairment in lung function in the absence of radiological signs of asbestos-related parenchymal disease cannot be attributed solely to smoking and that asbestos exposure plays a causal role.

A recent meta-analysis [35], which did not consider radiological findings, demonstrated independent significant effects of smoking as well as of asbestos exposure (i.e. a synergistic effect), both for forced expiratory flow (FEF_{25-75} , FEF_{50}) as well as thoracic gas volume (TGV) and RV/TGV . In this analysis, the influence of asbestos exposure was stronger than that of smoking for FEV_1/VC and airway resistance, whereas smoking had a stronger effect on FEF_{25-75} . Evidence for a synergistic detrimental effect of smoking and asbestos exposure on airflow limitation has also been reported in several additional studies (FEV_1 [62,41,61,63,64], FEV_1/VC [65,66,9,10,4,25,61,26], FEF_{25-75} [66,3,25,10,43] and FEF_{75-85} [66,3]).

It has to be acknowledged that our study does not allow answering the question whether the observed statistically significant lung function impairments at the population level are also of clinical relevance at the individual level. Indeed, in clinical practice the diagnosis of an obstructive defect requires a FEV_1/FVC of less than 70% and a FEV_1 over 80% from predicted is considered to represent mild impairment in an individual [67]. Our pooled estimates are within the normal limits applied to individuals (even when considering the lower limits of the confidence interval). Small decreases in group mean values however do not preclude clinically important disease. For example a group of workers exposed to asbestos with moderate dyspnoea had mean FVC of 96%,

mean FEV₁ of 94% and mean FEV₁/FVC of 95% of predicted [68], which are similar to our pooled estimates. In one study, lung function impairments, particularly airflow obstruction, have been associated with increased mortality in asbestos exposed workers [69].

Conclusions

We conclude that asbestos exposure causes restrictive as well as obstructive lung function impairment. Asbestos-exposed workers may present lung function impairments even in the absence of radiological evidence of asbestos-related pleural fibrosis or asbestosis.

Our systematic review demonstrates that despite the large number of studies about the health hazards from occupational exposure to asbestos, there is a need for further research, especially on the role of smoking, occupational co-exposure (e.g. other mineral dusts, welding fumes) and possible synergistic effects on the development of functional impairment, particularly chronic airway obstruction, in asbestos-exposed workers. Such studies should include measurement of CO diffusion capacity, airway resistance and flow volume curves in a consistent approach. Furthermore, our study underlines the necessity for an international agreement on lung function reference values within the individual ethnic groups, to facilitate comparison between different studies.

Abbreviations

CI: confidence interval; D_{L, CO}: CO diffusion capacity; DPT: diffuse pleural thickening; FEF: forced expiratory flow; FEV₁: forced expiratory volume in the first second; FVC: forced vital capacity; HRCT: high resolution computed tomography; PP: pleural plaques; RV: residual volume; SD: standard deviation; SE: standard error; SVC: slow (relaxed) vital capacity; TGV: thoracic gas volume; TLC: total lung capacity; VC: vital capacity; X-ray: chest radiograph

Acknowledgements and Funding

We thank Kevan Wiley for proof-reading our manuscript. There has been no external financial support or funding of the study, any person who contributed to this study or the preparation of the manuscript.

Authors' contributions

All authors had full access to all data. XB had the original idea for the paper and vouches for the integrity of the analysis. DW, UM and MVG extracted and analysed the data. All authors collaborated in interpreting the data and writing the manuscript and read and approved the final manuscript.

Competing interests

The authors declare that they have no competing interests.

Zusammenfassende Darstellung der Publikation „Lung function in asbestos-exposed workers, a systematic review and meta-analysis“ – breiterer Kontext und weiterführende Ergebnisse.

Hintergrund

Unter der technischen Bezeichnung „Asbest“ (griechisch: asbestos, unvergänglich) werden mineralogisch verschiedene faserförmige Silikate subsummiert. Mitte des vergangenen Jahrhunderts wurde Asbest aufgrund seiner hervorragenden Materialeigenschaften zu einem industriell viel verwendeten Ausgangsmaterial, vor allem im Baugewerbe (Asbestzement „Eternit“, Wellplatten etc.). In den 1960er- und 1970er-Jahren erreichte der Verbrauch in Deutschland ein Plateau mit etwa 200000 Jährestonnen. Expositionen bestanden v. a. in der Asbestaufbereitung, in der Herstellung und Bearbeitung von Asbestzement, Bremsbelägen, Asbest-Textilprodukten, Platten und Spritzmassen zur Wärme- und Feuerdämmung sowie von anderen säure- und hitzebeständigen Materialien und dergleichen mehr. Mit über 90% des Verbrauchs stand Serpentinasbest (Chrysotil=Weißasbest, Magnesiumsilikat) in Deutschland ganz im Vordergrund; Amphibolitasbeste (Krokydolith= Blauasbest, Natrium-Eisen-Silikat; Antophyllith, Amosit=Braunasbest) spielten mengenmäßig eine deutlich geringere Rolle.

Erst Ende der 1980er-Jahre kam es zu einer drastischen Reduktion des Asbestverbrauchs, jedoch war die berufliche Exposition gegenüber faserförmigem Asbeststaub bis Anfang der 90er Jahre noch weit verbreitet. Seit dem Herstellungs- und Verwendungsverbot von 1993 besteht ein weitestgehender Expositionsstop. Relevante Expositionen kommen heute noch bei Sanierungs- und Abbrucharbeiten vor, die unter Beachtung strenger Gesundheitsschutzregularien nach der Gefahrstoffverordnung (TRGS 519) auszuführen sind.

Asbestfasern werden per inhalationem inkorporiert und zunächst in den Atemwegen und Alveolen deponiert. Sie gelangen entlang gerichteter anatomischer Bronchial- und Lungenstrukturen (Bronchien, Bronchiolen, Alveolen) in das Lungeninterstitium und können dort weitertransportiert werden und bis zur Pleura und darüber hinaus wandern. Asbestfasern verursachen in den Bronchien, Bronchiolen, im Alveolarraum und in den angrenzenden Räumen anhaltende Entzündungsreaktionen, welche eine

chronische Bronchitis, Bronchiolitis und Alveolitis mit peribronchiolärer und panalveolärer Fibrose zur Folge haben. Dabei ist für alle genannten Erkrankungen eine mittlere Latenzzeit von etwa 3 Jahrzehnten mit breiten Streubereichen zu berücksichtigen. Letzteres ist der Grund, weshalb hierzulande der Gipfel der Erkrankungshäufigkeit erst in den nächsten Jahren erreicht wird.

Die Anzahl der arbeitsbedingt früher in Deutschland anhaltend gegenüber Asbest Exponierten beträgt mindestens eine Million. Allein in der sog. Gesundheitsvorsorge (GVS), vormals Zentrale Erfassungsstelle Asbest (ZAs), der gesetzlichen Unfallversicherung sind bisher etwa 500.000 ehemals asbestexponierte Arbeitnehmer erfasst, die nachgehenden arbeitsmedizinischen Untersuchungen zugeführt werden.

Asbestbedingte Berufskrankheiten

Asbest-bedingte Erkrankungen der Atmungsorgane können in benigne und maligne Pleura- und Lungenkrankheiten unterteilt werden. Unter der Berufskrankheit (BK) Nr. 4103 der Berufskrankheitenverordnung (BKV) werden hyaline und/oder kalzifizierte Pleuraplaques, die diffuse Pleurahyalinose und die Asbest-Lungenfibrose zusammengefasst. Auch die Asbestpleuritis, welche im akuten Stadium mit rezidivierenden Pleuraergüssen assoziiert sein kann, wird unter der BK Nr. 4103 subsummiert. Letztere ist oft schwer vom Mesotheliom abzugrenzen.

Als Asbest-assoziierte Malignome sind der Kehlkopfkrebs, der Lungenkrebs (BK Nr. 4104) und die Mesotheliome der serösen Häute, insbesondere der Pleura, aber auch des Perikards und des Bauchfells (BK Nr. 4105) zu nennen. Voraussetzung für die Anerkennung Asbest-bedingter Lungen- und Kehlkopfkarzinome als Berufskrankheit ist eine Einwirkung von in der Regel ≥ 25 Faserjahren, das Vorliegen einer Asbestose, Asbest-assozierter Pleuraveränderungen oder einer Minimalasbestose (Merkblatt BK Nr. 4104) (Bundesministerium für Arbeit und Sozialordnung 1997).

Im aktuellen Berufskrankheitengeschehen finden sich für 2010 folgende Anzeigehäufigkeiten: 3732 Fälle von Asbestose/asbestbedingten nicht malignen Pleuraerkrankungen (2009: 3971 Fälle), 3709 Fälle von Lungenkrebs oder Kehlkopfkrebs (2009: 3909 Fälle), 1479 Fälle von Mesotheliom (2009: 1474 Fälle). Als Berufskrankheit anerkannt wurden im selben Jahr 1749 (2009: 1986), 719 (2009: 708) bzw. 931 (2009: 1030) Erkrankungen dieser Entitäten. Eine neue Rente wurde in 421, 676 bzw. 876 Fällen bewilligt (Deutsche Gesetzliche Unfallversicherung (DGUV) 2011).

Unter der Voraussetzung der gegebenen Expositionskausalität, haftungsbegründenden und haftungsausfüllenden Kausalitäten bereitet die gutachterliche Einschätzung fortgeschrittener Asbest-bedingter Lungenkrankheiten in der Regel keine Schwierigkeiten. Als Lungenfunktionsstörung resultiert hierbei meistens eine Restriktion mit Einschränkung aller Lungenvolumina, also der totalen Lungenkapazität (TLC), des Residualvolumens, der Vitalkapazität (FVC, VC) und des intrathorakalen Gasvolumens (IGV) sowie der Diffusionskapazität (DL,co).

Aktuelle Kontroversen in der Begutachtung asbestbedingter Erkrankungen

Deutlich weniger Einigkeit besteht in der Bewertung der lungenfunktionellen Veränderungen in Fällen von nur gering ausgeprägten radiologischen Befunden bzw. mit führender obstruktiver Ventilationsstörung.

In der Begutachtungspraxis wurde bisher in der Regel davon ausgegangen, dass Asbest-Exponierte ohne wesentliche Auffälligkeiten im Röntgenthoraxbild keine relevanten asbestbedingten Krankheitssymptome und Lungenfunktionseinschränkungen haben können. Dies wird vielerorts auch für Personen mit geringgradigen Pleuraplaques angenommen.

Eine Reihe aktueller klinisch-wissenschaftlicher Studien befasst sich mit neuen, deutlich sensitiveren radiologischen (HRCT) und funktionsanalytischen (DL_{CO}) Verfahren sowie zeitgemäßen Lungenfunktionssollwerten und stellen dies auch in Verbindung mit einer immer noch leicht steigenden Zahl Betroffener. Sowohl die Rolle der obstruktiven Lungenfunktionsveränderungen als auch der Zusammenhang zwischen Exposition, radiologischen Befunden und Einschränkungen der Lungenfunktion werden zunehmend diskutiert. So beschrieben z.B. Begin et al. (Begin et al. 1983) unter Nie-Rauchern mit Lungenasbestose eine bis in den Perialveolarraum fortschreitende peribronchiolare Fibrose und eine Akkumulation mononukleärer Zellen in die Alveolarräume. Als Ausdruck der Bronchiolitis fanden sie eine Verdickung der Wände und Irritationen der kleinen Atemwege (Begin et al. 1983). Diese Prozesse gehen jedoch in frühen Krankheitsstadien und nach kurzen Expositionszeiten nicht mit röntgenologischen Auffälligkeiten einher. Sie laufen zusammen individuell mit unterschiedlicher Geschwindigkeit ab und können auf einem bestimmten Niveau persistieren. Es gibt

Hinweise darauf, dass die individuelle Suszeptibilität für den Verlauf der Asbesterkrankung innerhalb bestimmter Belastungsgrenzen einen hohen Stellenwert einnimmt.

Im Gegensatz zu der oben beschriebenen Praxis der Begutachtung asbestbedingter Erkrankungen, stützen neue Studien die Annahme, dass der röntgenologisch sichtbare Befall der Pleura Folge der Wanderung der Asbestfasern durch das Lungeninterstitium mit begleitenden inflammatorischen Prozess und mikroskopisch z. T. erkennbaren, z. T. auch submikroskopischen Veränderungen der Bronchien, Alveolen und des Lungeninterstitiums ist (Churg et al. 1985). Daraus resultieren unterschiedliche morphologische und funktionelle Befunde, wobei mehr bronchial, alveolär oder interstitiell akzentuierte Krankheitsbilder vorkommen können. Hierbei sind Lungenfunktionseinschränkungen auch dann zu erwarten, wenn sich das Lungeninterstitium und die Pleura konventionell röntgenologisch noch unauffällig darstellen. Als frühester Ausdruck eines asbestbedingten Lungenschadens ist eine Einschränkung der Diffusionskapazität zu erwarten (Dujic et al. 1992).

Ferner zeigen Studien, dass asbestbedingte Lungengerüstprozesse in fortgeschrittenen Stadien Deformierungen des Bronchialbaumes und der Alveolarräume nach sich ziehen können. Nicht selten treten eine chronische Bronchitis mit oder ohne obstruktive Ventilationsstörung, z.T. auch emphysematöse Veränderungen hinzu. Insgesamt sind im Zusammenhang mit fortgeschrittenen asbestbedingten Lungengerüsterkrankungen alle Varianten von Lungenfunktionsstörungen denkbar und lassen sich durch den Krankheitsprozess erklären.

Ausgangsfrage

Zur integrativen Interpretation der zur Verfügung stehenden Literatur wurde die vorgelegte metaanalytische Untersuchung durchgeführt. Auf der Basis einer Bewertung soll dabei eine Handlungshilfe für die gutachterliche Beurteilung des Einzelfalls geben werden. Von wesentlicher Bedeutung ist dabei die Beantwortung der Frage, ob unter Asbest-Exponierten ohne röntgenologisch sichtbare Lungenveränderungen bzw. lediglich mit röntgenologisch nachweisbaren Pleuraplaques (umschriebenen Pleurafibrosen) oder diffuser Pleuraverdickung mit dem heutigen sensitiven Instrumentarium Einschränkungen der Lungenfunktion festzustellen sind. Außerdem inter-

essiert, inwiefern auch die Atemwege in Form einer objektivierbaren Obstruktion in ehemals Asbest-exponierten Kollektiven betroffen sind.

Als problematisch bei der Bewertung der Vielzahl neuer Studien zum Zusammenhang zwischen Asbestexposition, lungenfunktionellen und radiologischen Veränderungen erweisen sich die ausgesprochene Heterogenität zwischen den einzelnen Studien in Bezug auf die Asbest-Exposition (Länge, Art und Dauer), die Kollektivzusammensetzung, die eingesetzte Diagnostik, die erfassten klinischen Symptome und funktionellen Parameter sowie deren Referenzwerte.

Ergebnisse der Metaanalyse

Mit Hilfe der elektronischen Datenbanksuche, ergänzt durch die manuelle Suche u.a. in Kongressbänden, Referenzlisten und eigenen Archiven konnten initial 588 potentiell relevante Veröffentlichungen identifiziert werden. Nach der systematischen Überprüfung aller Referenzen und Anwendung der Ein- und Ausschlusskriterien wurden 29 Arbeiten mit insgesamt Daten von 9921 Personen in die Metaanalyse aufgenommen. Dabei betrachtete ein Teil der Untersuchungen Arbeiten aus einer bestimmten Berufsgruppe, z.B. Isolierer oder Werfarbeiter, wohingegen andere Autoren mehrere Berufsgruppen in einer Untersuchung zusammengefasst haben.

Vitalkapazität

Die Vitalkapazität war der am häufigsten entsprechend unserer Qualitätskriterien für die Aufnahme in die Metaanalyse untersuchte Parameter. Erwartungsgemäß zeigte sich insgesamt bei asbestexponierten Arbeitern eine Verminderung der Vitalkapazität im Vergleich zur nichtbelasteten Allgemeinbevölkerung. Die Einschränkung war am stärksten ausgeprägt in der Gruppe mit radiologischen Zeichen einer Asbestose (86,5% des Sollmittelwertes; 95%CI 83,7-89,4); jedoch war bereits in der Gruppe Asbestexponierter ohne radiologisch fassbare Veränderungen eine signifikante Veränderung festzustellen (95,7% des Sollmittelwertes; 95%CI 93,9-97,3). Die Subgruppenanalyse nach angewendeten radiologischen Verfahren (konventionelles Röntgenbild oder Computertomographie) zeigte erniedrigte Werte der Vitalkapazität in allen drei radiologischen Kategorien (1. keine pathologischer Befund, 2. pleurale Veränderungen und 3. Asbestose mit und ohne Pleurabeteiligung), wobei die Abwei-

chungen bei Berücksichtigung der konventionellen Röntgenbilder stärker ausgeprägt waren als bei Zugrundelegung der CT-Befunde.

FEV1

Auch für die FEV1 konnte gezeigt werden, dass ein Abfall im Vergleich zum Referenzkollektiv schon bei Asbestexponierten ohne radiologische Auffälligkeiten festzustellen ist. Der Abfall nimmt analog zur Schwere des Röntgenbefundes zu. Auch für diesen Parameter ließen sich Unterschiede in Abhängigkeit von der verwendeten radiologischen Methode feststellen. Besonders ausgeprägt waren diese Unterschiede in der Gruppe mit ausschließlich pleuralen Veränderungen (Pleuraplaques oder diffuse Pleurafibrose); die Werte der Fälle, die anhand des konventionellen Röntgenbildes diagnostiziert wurden, waren annähernd 10% niedriger als jene, bei denen die Computertomographie eingesetzt wurde (83,9% des Sollmittelwertes; 95%CI 77,2-90,5 vs. 93,7% des Sollmittelwertes; 95%CI 87,9-99,9).

FEV1/VC

Die relative Einsekundenkapazität (FEV1/VC) wurde deutlich seltener als die o.g. Parameter in einer für eine Metaanalyse geeigneten Weise berichtet. Die verwertbaren Arbeiten zeigten eine geringfügige Reduktion der relativen Einsekundenkapazität bereits im Kollektiv der exponierten Arbeiter ohne radiologische Veränderungen und ohne wesentliche Abnahme in den Gruppen mit pleuraler und/oder parenchymaler Fibrose. Eine Abhängigkeit vom angewendeten radiologischen Verfahren war für diesen Parameter weniger deutlich erkennbar.

Einflussfaktor Rauchen

Zur Abschätzung des Rauchens als Einflussfaktor auf die untersuchten Parameter betrachteten wir getrennt Arbeiten mit einem Nichtraucheranteil von mehr als 25% und solche mit weniger als 25%. Dabei führten wir eine entsprechende Subgruppenanalyse durch. Abgesehen von zwei Ausnahmen beinhalteten alle Studien Daten von Rauchern und/oder Exrauchern. Der Anteil der Nichtraucher in den Untersuchungen reichte von 3 bis 100 % und lag im Median bei 26,2%. Die Höhe des Zigarettenkonsums wurde in 18 Arbeiten angegeben und reichte von 14,0 +/- 11,9 bis 38,9 +/- 29,4 Packungsjahre. Die Auswertung zeigte eine höhergradige Lungenfunktion einschränkung in den Arbeiten, die einen Nichtraucheranteil von mehr als 25% in den

Kollektiven ohne radiologischen Nachweis asbestbedingter Veränderungen bzw. mit alleinigem Pleurabefall aufwiesen. Im Falle einer Asbestose fanden sich niedrigere Lungenfunktionswerte in der Subgruppe mit niedrigerem Nichtraucheranteil. In der Regressionsanalyse des Effektes des Anteils von Nichtrauchern auf die FEV1 gab es einen statistisch nicht signifikanten Trend zu einer geringeren Funktionseinschränkung des Parameters bei höherem Anteil an Nichtrauchern.

Die Daten bzgl. der Expositionsdauer waren sehr heterogen und oft unvollständig. Regressionsanalytisch lassen sich niedrigere Werte für Vitalkapazität und FEV1 mit zunehmender Expositionsdauer vermuten.

Insgesamt zeigt die Metaanalyse eine signifikante Verminderung von VC, FEV1 und der FEV1/VC unter asbestexponierten Arbeiter im Vergleich mit den Referenzwerten, erhoben an der Allgemeinbevölkerung. Diese Einschränkungen weisen nur eine grobe Abhängigkeit vom radiologischen Befund auf.

Diskussion und Schlussfolgerungen

Die metaanalytische Auswertung der Daten von nahezu 10.000 Asbestexponierten zeigt, dass eine Asbestexposition sowohl zu restriktiven als auch zu obstruktiven Ventilationsstörungen führt. Asbestexponierte können auch bei Fehlen von radiologisch nachweisbarer Pleurafibrose oder Asbestose Lungenfunktionseinschränkungen aufweisen.

Die systematische Auswertung zeigte, dass trotz der Vielzahl von Studien über die Gesundheitsgefahren durch berufliche Asbestexposition ein Bedarf an weiterer Forschung besteht. Dies gilt vor allem hinsichtlich der synergischen Rolle des Rauchens und von beruflichen Co-Expositionen (z.B. andere Mineralstäube, Schweißrauche) bei der Entstehung von Lungenfunktionseinschränkungen.

Solche Studien sollten die standardisierte Messung der CO-Diffusion, des Atemwegswiderstandes und die Aufzeichnung der Fluss-Volumen-Kurven entsprechend internationaler Qualitätskriterien beinhalten. Des Weiteren verdeutlicht die Metaanalyse die Notwendigkeit von zeitgemäßen und international einheitlichen Lungenfunktionssollwerten, um eine aktuelle Interpretation und einen Vergleich zwischen verschiedenen Kollektiven zu ermöglichen.

Bisherige Auswirkungen und Einflüsse der Metaanalyse

Unter Federführung der Deutschen Gesellschaft für Arbeitsmedizin und Umweltmedizin und der Deutschen Gesellschaft für Pneumologie wurde in den Jahren 2008 - 2010 in einem Konsensusprozess unter der Schirmherrschaft der AWMF die S2k-Leitlinie „Diagnostik und Begutachtung Asbest-bedingter Berufskrankheiten“ entwickelt (http://www.awmf.org/uploads/tx_szleitlinien/002-038m_S2k_Diagnostik_und_Begutachtung_asbestbedingter_Berufskrankheiten_2010-12.pdf). Dabei flossen Teile dieser Arbeit in den Diskussionsprozess ein.

Entsprechend der heterogenen Datenlage der internationalen Literatur wurden die Fragen der asbestbedingten obstruktiven Lungenfunktionsveränderungen sowie die Möglichkeit relevanter Lungenfunktionseinschränkungen in Abwesenheit fassbarer radiologischer Veränderungen kontrovers diskutiert. U.a. wird in der neuen S2k-Leitlinie die Ergebnisse der Auswertung der vorliegenden Metaanalyse berücksichtigend die Möglichkeit auch rein obstruktiver Ventilationsstörungen sowohl bei einer Fibrose der Lunge als auch der Pleura visceralis explizit erwähnt. Ferner wird angeführt, dass eine umschriebene Verminderung der Lungenfunktion auch ohne eine im konventionellen Röntgenbild fassbare Veränderung als Expositionsergebnis auftreten kann. Insgesamt wird in der neuen Leitlinie im Vergleich zur früheren Begutachtungspraxis ein stärker multimodaler Ansatz zur Diagnostik asbestbedingter Erkrankungen und der Bewertung ihrer Auswirkungen verfolgt. Gleichberechtigt sollen demnach Anamnese, klinische Symptome, Lungenfunktionsveränderungen (Bodyplethysmographie und Diffusionskapazitätsmessung), Belastungsuntersuchung mit Blutgasanalyse und Spiroergometrie und die aktuelle Therapie des Versicherten berücksichtigt werden.
